NITROGEN FIXATION

Nitrogen fixation is the conversion of diatomic nitrogen (N₂) into ammonia (NH₃), which is then used for biosynthesis of organic compounds. See entry “[Nitrogen](#)” for further reading.

Synonyms

Gossan; Ore deposits; Oxidation zone; Supergene enrichment

Definition

Ore deposits are natural enrichments of chemical elements of economic interest. While all natural elements are present in certain background concentrations in rocks and minerals, they are typically not economically extractable at these levels. Geological processes may lead to enrichments of elements in such a way that orebodies are formed from which large quantities of elements may be extracted at a much lower cost. The formation of orebodies generally occurs in three steps: (1) element extraction from a large volume of rock or melt; (2) transport of elements; (3) deposition of elements in a volume of rock much smaller than the extracted volume. These steps may occur in magmatic melts, hydrothermal systems, diagenetic environments, and at the Earth's surface. Melts, solutions, gases, and solid phases (minerals) may be involved in these processes. In many cases, ore forming processes occur in magmatic and hydrothermal systems well beyond the temperature limit of microbial growth. However, important ore forming systems are also known within the temperature realm of microbial life (maximum 121°C). These are mainly confined to sedimentary and diagenetic environments and the low-temperature end of hydrothermal systems. A microbial involvement in the different

steps of ore formation may be due to direct interaction, i.e., ore precipitation as a result of microbial activity. On the other hand, indirect influences of life may include the conditioning of the environment (e.g., oxidizing atmosphere), allowing transport of certain elements in a soluble form, and so influencing ore forming processes in systems where microbes cannot live. During the weathering of ore deposits under near-surface conditions, microbes may also play an important role. In general, the direct involvement of microbes in ore formation is one of catalyzing redox reactions such as the oxidation of Fe and Mn and the reduction of S, Cr, and U. The role of low-temperature redox fronts as sites of ore formation and availability of energy for microbes have been reviewed by Hofmann (1999).

The possible role of microbes in ore precipitation has long been recognized (Macqueen and Coope, 1985; Southam and Saunders, 2005). Precipitation of ore minerals as a direct result of microbial activity can be inferred from the fact that many microbes can harvest energy from redox reactions, leading to immobilization of elements. Such reactions include the reduction of U(VI), Cr(VI), and Au(I) (Kashefi and Lovley, 2000; Kashefi et al., 2001; Labrenz et al., 2000; Moreau et al., 2004), the reduction of As and Se (Stolz and Oremland, 1999), and possibly also the indirect reduction of oxidized elements by H₂S (Mohagheghi, 1985).

Arsenic is an important element in ore deposits. Reduced arsenic (As-I) leads to the precipitation of Ni, Co, Fe, and other elements as arsenides. Native As, As(0), also is relatively common. Native As of distinct low-temperature origin occurs in a stratigraphically well-defined horizon over approximately 300 km² in the Middle Triassic of southern Germany/N Switzerland (Hofmann, 1989a; Hofmann and Gehlen, 1993). While the microbial reduction of As(V) to As(III) is well known

Ores, Microbial Precipitation and Oxidation, Figure 1 Banded iron formation. Bands of black hematite, red chert, and yellow (altered) riebeckite, a metamorphic mineral. Mt. Brockman, Hamersley Range, Western Australia. Width of sample is 9 cm. (Photograph by Peter Vollenweider.)

(Oremland et al., 2005), an involvement of microbes in the reduction of As to lower valence states is also known (Bentley and Chasteen, 2002) and may possibly play a role in the precipitation of arsenides and native As.

Oxidation reactions leading to ore mineral precipitation are particularly significant in the case of Fe (Konhauser, 1998; Konhauser et al., 2002; Widdel et al., 1993) and Mn (Tebo et al., 1997).

There are still other possible mechanisms of microbial involvement in ore precipitation such as the microbial destruction of complexants, e.g., of thiosulfate in the case of gold and possibly silver (Lengke and Southam, 2005). Similar processes may apply for cyanate.

Ore deposit types for which microbial involvement in ore deposition has been postulated

Banded iron formations (BIFs) are mainly of Proterozoic age and are temporally related to the oxygenation of the atmosphere and the sea (Figure 1). BIFs are also known from the Archean to the Phanerozoic. The involvement of photosynthesizing microbes in the origin of BIF is controversial. Konhauser et al. (2002) demonstrated the feasibility of microbial precipitation. Anoxygenic photosynthesis (Widdel et al., 1993; Kappler et al., 2005) has been proposed as a major possible process. In a discussion, Klein (2005) concludes that there is no proof of direct microbial iron oxidation in the formation of BIFs. The various genetic models are discussed by Beukes (2004). Iron isotope studies also do not provide a signal distinctive from that of nonbiological fractionation

(Anbar, 2004). Even though there is no direct proof of microbial precipitation, it is very likely that the oxidant involved in the transformation of mobile Fe(II) to immobile Fe(III) was of biogenic origin.

Other iron deposits. Phanerozoic sedimentary iron deposits commonly display oolitic or pisolitic textures and are of syngenetic–diagenetic origin. Dahanayake and Krumbein (1986) proposed a biogenic involvement in ore precipitation based on the presence of filaments in ooids.

Sedimentary manganese deposits including ferromanganese nodules. The coincidence of environmental oxidation in the Proterozoic with the precipitation of the Kalahari manganese deposits, the world's largest manganese orefield, is taken as evidence that deposit formation was induced by biological oxygen production (Kirschvink et al., 2000; Schaefer et al., 2001).

Sandstone-hosted uranium deposits: Major sandstone-hosted uranium deposits most commonly occur in Mesozoic and Cenozoic rocks in the western USA, but also in Australia, southern France, and the former Soviet Union. A summary of uranium deposit types is found in (Dahlkamp, 1993). The sandstone-hosted deposits are often formed where detrital terrestrial organic matter produced local reducing environments. Sandstone-hosted uranium deposits also occur in Proterozoic rocks of the Francevillian Basin of Gabon, where the reducing traps are related to hydrocarbon-bearing faults. Phanerozoic deposits exist in tabular and roll-type (Figure 2) geometries. Closely related are redox-boundary controlled uranium deposits in altered phonolitic rocks at Pocos de Caldas, Brazil (Figure 3, see Waber et al., 1992). Both for roll-type deposits (Goldhaber et al., 1978; Reynolds et al., 1982; Warren, 1972) and tabular U–V deposits (Goldhaber et al., 1990; Meunier et al., 1987; Mohagheghi et al., 1985; Wanty et al., 1990) biogenic versus abiogenic reduction processes have been discussed. Considering that these deposits formed in near-surface environments at close to ambient temperatures that they do contain sulfide minerals indicating low-T sulfate reduction, and that they represented redox fronts providing a lot of chemical energy, the absence of a microbial involvement would be surprising. However, no clear biosignatures have been described. Light sulfur isotopes from these deposits have been interpreted biologically (Jensen, 1958; Rackley, 1972), but also nonbiologically (Warren, 1971). The possible involvement of intermediate-valence sulfur species (e.g., thiosulfate), through biological (Bak and Cypionka, 1987) or nonbiological pathways, seem possible.

Unconformity-related uranium deposits: For this major type of uranium deposits (mainly occurring in the Proterozoic of Canada and Australia) a microbial involvement appears generally unlikely due to high formation temperatures of 100–250°C (Suzuki and Banfield, 1999). An involvement of microbial activity has been postulated by Donnelly and Ferguson (1980). There is an interesting paragenetic similarity (predominance of U, Co, Ni, Bi,

Ores, Microbial Precipitation and Oxidation, Figure 2 Roll-front type uranium deposit, South Texas, formed by infiltration of oxidized waters into permeable reduced sandstones. Red denotes oxidized sandstone, black denotes the zone of uranium mineralization, and green is the unaltered reduced rock. (From Hofmann 1999, based on Dahlkamp, 1993.)

Ag) with reduction spheroids, for which a microbial involvement appears likely.

Deep-sea hydrothermal vents: Sulfide-rich ore deposits originating from the venting of metal-rich hydrothermal fluids in the deep sea are dominated by Fe–Cu-sulfides (with Au, Pb–Zn-rich in back-arc and sedimentary settings). Based on sulfur isotope data, a part of the sulfide sulfur is of microbial origin (Fallick et al., 2001; Taylor, 2004). In case of Irish-type carbonate-hosted massive sulfide deposits, similar evidence has been provided by Wilkinson et al. (2005).

Mississippi-Valley-Type (MVT) and related Pb–Zn deposits. MVT deposits are formed not only from basinal brines, mainly in carbonate rocks, but also in sandstones at the edge of sedimentary basins. Ore deposition is due to cooling, wall-rock reactions, fluid mixing, or

a combination thereof (Burstein et al., 1993; Leach et al., 1996). The possible role of microbial sulfate reduction in the precipitation of ores is controversial. Reports on fossilized microbes (Kucha et al., 2005) and sulfur isotopic variations have been interpreted as proof of biogenic involvement, e.g., in salt caprock-associated (Saunders and Swann, 1994) and alpine type deposits (Schroll, 1996). Features of thermochemical sulfate reduction (TSR) as compared with biogenic sulfate reduction (BSR) are discussed by (Machel, 2001), concluding that most MVT deposits are due to TSR, while BSR produces iron-dominated sulfide accumulations. The range of MVT deposits is very large and ore textures range from coarsely crystalline to submicroscopic. This variability, also including sulfur isotopes, and the near-surface origin of a part of the deposits, may indicate that both TSR and

Ores, Microbial Precipitation and Oxidation,

Figure 3 Uraninite-rich nodule in altered phonolite from the reduced side of the redox front at Poços de Caldas, Minas Gerais, Brazil. A microbial origin of this local uranium enrichment appears possible, based on its isolated occurrence, low-T origin, and geometry. Field of view is 17 mm.

BSR are involved in MVT genesis. Clear criteria for a differentiation have yet to be found.

Low-temperature hydrothermal ore deposits. Low-temperature (epithermal) ore deposits are formed in a temperature range that may overlap with possible microbial growth. Fluctuating systems may provide conditions at least temporarily suitable for microbes. Reports of microbial activity in such occurrences are rather scarce. Hofmann (1989b) reported filamentous forms from the Krunkelbach uranium deposit in (Germany, Figures 4 and 5) and similar features were observed in other Schwarzwald occurrences (Reitner, 2004). Based on morphological similarities, a microbiological origin of features described as “stalactites” from Creede, Colorado (Campbell and Barton, 1996; Hofmann, 1989b; Hofmann et al., 1998; Reitner, 2004), may be ascribed to be due to mineralized microbial fabrics (Hofmann et al., 2008).

Reduction spheroids. Small-scale reduction phenomenon in red beds with accumulations of numerous elements (U, V, Co, Ni, As). Due to geochemical similarities with sandstone-hosted U-V deposits and certain low-T hydrothermal veins, these features of probable microbial origin may present an important genetic link see *Reduction Spheroids*.

Black shales. Sediments deposited under oxygen-poor to oxygen-free conditions, with low sedimentation rates, are typically enriched in redox-sensitive elements such as U, V, and Mo (Lehmann et al., 2007; Leventhal, 1998). Trace element-rich black shales are a result of the activity of sulfate-reducing bacteria in the water column and/or at the water-sediment interface. Typically, black shales are of subeconomic grade, e.g., the U-enriched Cambrian Alum Shale of Scandinavia. Under conditions of extremely low sedimentation rates, economic ore grades may be reached as in case of the early Cambrian of China (Lehmann et al., 2007). Secondary processes such as deep diagenetic redox fronts (Kupferschiefer of Germany and Poland) or supergene enrichment, e.g., at Ronneburg and

Marsberg, Germany (Stribny and Puchelt, 1991), may enrich black shale protores to economic grades.

Weathering and supergene enrichment of ore deposits

Long after the formation of orebodies, interactions with their environment may take part; most commonly observed are weathering and supergene enrichment. In certain cases the processes of weathering lead to a secondary, near-surface enrichment of the ore (supergene enrichment) along a redox front between unaltered

Ores, Microbial Precipitation and Oxidation,

This oxidation zone mineral shows a peculiar filament-like form indicating the incrustation of microbial filaments. Maximum field of view is 10 cm. (Photograph by Peter Vollenweider.)

and oxidized ores. Supergene enrichment may be critical for economic extraction. An involvement of microorganisms in the processes of ore oxidation and supergene enrichment has been reported in many cases from terrestrial (Sillitoe et al., 1996) and marine settings (Glynn et al., 2006). Microbial sulfide oxidation is well studied, mainly with reference to biomining and acid rock drainage.

Probably the most significant microbial process in the oxidation zone is the oxidation of sulfide (Nordstrom and Southam, 1997) and ferrous minerals. Subsurface filamentous fabrics SFF likely of microbial origin are very common in oxidation zone mineral assemblages (Figures 6 and 7). Such morphological evidence of microbial activity in the oxidation zone of ore deposits is

Ores, Microbial Precipitation and Oxidation,

corroborated by stable isotopic data (Rainbow et al., 2006; Melchiorre and Williams, 2001; Melchiorre et al., 2001).

In the zone of supergene enrichment, oxidized fluids from near-surface parts of the ore interact with reduced, unaltered ore (commonly sulfides). A microbial involvement in such processes of supergene enrichment has been demonstrated in the Morenci copper mine, Arizona (Enders et al., 2006), and in the case of ore-grade supergene sphalerite from Nevada (Bawden et al., 2003). Based on nannobacteria-like forms, Sillitoe et al. (1996) assumed a microbial origin of cementative copper ore at Chuquicamata, Chile.

Conclusions

It is a fact that microorganisms do perform transformations (mainly redox changes) for a number of key elements in ore deposits. In many cases such microbial transactions are advocated to explain the genesis of orebodies, and in other cases they are excluded. A critical review of the existing literature indicates, however, that proofs of microbial involvements often are weak, while the probability of microbial involvement, based on knowledge in microbial ecology, is highly likely. Clearly, the range of arguments to prove or disprove biological interactions in ore deposit formation needs to be extended.

Organomineral formation

Definition

Organomineralization is a process of mineral formation mediated by organic matter (OM), independent of the living organisms which the OM derives from. The organic compounds may be excretion products or detached parts of living organisms, or relics and by-products of dead organisms that have been released into waters or incorporated into soils, sediments, or rocks. Abiotic OM may also induce the formation of minerals in nature or in the laboratory.

Organominerals are the mineralic products of organomineralization. They should be distinguished from minerals precipitated through inorganic processes, among which some may contain OM entombed or complexed during crystal growth, from organic minerals such as graphite and from biominerals produced by living organisms.

Genesis of the organomineralization concept

The term *organomineralization* was introduced in 1993 by Trichet and Défarge (1995) at the 7th International Symposium on Biomineralization. It aimed to denote the processes of mineral formation that are similar to biomineral formation by living organisms, because induced by organic templates, compartments and compounds (*Biomineralization*, qv), but distinct because occurring in waters, soils, sediments or rocks, independently of the living organisms which the mineralizing OM derives from. The substantive *organomineral* was also introduced at the same symposium to refer to the mineral products of organomineralization, to be distinguished from the biominerals produced by living organisms (Défarge and Trichet, 1995). These definitions were supported by illustrations of organomineral formation processes including (Défarge and Trichet, 1995; Trichet and Défarge, 1995) diagenetic calcification of gastropod fecal pellets; post-mortem encrustation of cyanobacterial filaments, fish organs, and soft tissues of trilobites by calcium carbonate (CC), calcium salts of fatty acids, or pyrite; formation of CC bodies and phosphate pellets under the influence of sedimentary OM; intervention of soil organic compounds in the crystallization of aluminum and iron oxides and hydroxides; precipitation of metal oxides and sulfides following the demixion of organometallic complexes subjected to geothermal heating; and laboratory formation of CC ooids in the presence of OM rich in acidic groups.

The first hypotheses on the role of sedimentary OM in the precipitation of minerals in natural environments, believed to be analogous to that played by organic templates in biomineralization, were published in the 1960s in papers presented on the formation of calcareous microbial deposits, oolites, and coprolites (Trichet, 1967, 1968; Mitterer, 1968; for later references see Morse et al., 2007). These hypotheses were founded on the similarities in composition of the organic fraction of these carbonate bodies with that of biomineral matrices, which are both rich in acidic amino acids, and on earlier work evidencing that

dissolved organic compounds can favor CC precipitation from waters (see references in Mitterer, 1968; Trichet, 1968; or Trichet and Défarge, 1995).

A decisive step in this research and in the genesis of the concept of organomineralization was made, thanks to studies on carbonate formation in the modern lacustrine *microbialites* (qv) of Pacific atolls (Défarge and Trichet, 1995): The mineral fraction of these sediments was shown to be principally composed of magnesian calcite micrite clusters that had precipitated within the alveoli, on the wall surfaces of an organic honeycomb-like network formed by the reorganization of *extracellular polymeric substances* (EPS, qv) secreted by *cyanobacteria* (qv). These organic templates of precipitation thus had the same origin as those of CC biomineralization in cyanobacteria, which is associated with the cell sheath (Merz-Preiß, 2000). In addition, it was demonstrated that this OM fixed divalent metallic cations at acidic sites, whose affinities with calcium ions explain why they act as nucleation sites for CC biomineralization (Addadi and Weiner, 1992; Gilbert et al., 2005). When they can be individually observed, the magnesian calcite crystals were shown to grow with their *c*-axis perpendicular to the organic template (e.g., Défarge et al., 1996, Figure 5c), as is frequently observed in epitaxial CC biomineralization (Addadi and Weiner, 1992), e.g., on algal cell surfaces (Weiner and Dove, 2003). This process of micrite precipitation thus appeared analogous to carbonate biomineralization, although distinct because of being mediated by nonliving, sedimentary OM. These micrite organominerals were accompanied by tubular ones, resulting from the post-mortem encrustation of cyanobacterial filaments, which thus controlled the final mineral shape, and by biomineralized cyanobacterial sheaths (Défarge and Trichet, 1995). These carbonate microbialites thus revealed a continuum of mineralizing organic–mineral interactions in nature, from biomineralization through organomineralization processes (Défarge and Trichet, 1995; Défarge et al., 1996).

Organomineralization versus biomineralization

The existence of such continua among biomineralization processes *sensu stricto* had already been established: Lowenstam and Weiner (1989) distinguished “biologically controlled mineralization”, characterized by cellular controls on crystal nucleation and growth, delineated spaces of mineral formation, and specific habits of the biominerals produced, and “biologically induced mineralization”, which designates biotic processes that are not specifically designed for mineralization but result in mineral being formed. However, in these latter cases too, organisms exercised some control on mineral formation (Lowenstam and Weiner, 1989; Weiner and Dove, 2003).

Another continuum bridges biologically induced mineralization occurring through crystal nucleation on organic secretions outside of organisms (see Weiner and Dove, 2003, Figure 4), and organomineralization on sedimentary organic substrates derived from EPS described by

Défarge and Trichet (1995). The distinction between the two processes, however, is justified, as nucleating organic substrates may act remote in space and time from the organisms which they derive from, as in the examples documented by Trichet and Défarge (1995) for carbonate sediments or for metal minerals formed through geothermal heating of organometallic complexes.

In all cases of organomineralization, biotic processes (such as photosynthesis or sulfate reduction in the case of CC; Dupraz and Visscher, 2005) may also participate in solution supersaturation leading to crystal formation on the nonliving organic templates. However, the global process cannot be simply described as “biologically induced” when these nonliving substrates appear to play a necessary role in crystallization, in particular crystal heterogeneous nucleation, or cessation or confinement of crystal growth. In introducing the concept of organomineralization, Trichet and Défarge (1995) aimed to point out that organic matrices and compounds inherited from living organisms may retain mineralizing properties after they have been released into waters and incorporated into soils, sediments, and rocks.

Evolution of the organomineralization domain

The same year in which Trichet and Défarge (1995) introduced the term *organomineralization* at the 7th International Symposium on Biomineralization (1993), Reitner (1993) and then Reitner et al. (1995) at the same conference, hypothesized that organic matrix-mediated processes were responsible for carbonate automicrite and peloid formation in modern microbialites and sponge tissues from reef caves. These processes appeared analogous to those postulated for the precipitation of CC organominerals in Polynesian microbialites (Défarge and Trichet, 1995; Trichet and Défarge, 1995), and have therefore been considered organomineralization processes (Neuweiler et al., 1999; Reitner, 2004). Thereafter, a number of papers have documented CC organomineralization in natural environments or in the laboratory (see review in Défarge et al., 2009). New illustrations included for example, automicrite formation in Lower Cretaceous carbonate *mud mounds* (qv; Neuweiler et al., 1999) or calcification of the housing tubes of modern and fossil polychaete worms (Fischer et al., 2000). Riding (2000) and Schlager (2003) identified organomineralization as one of the main processes of carbonate precipitation in *microbial mats* (qv) and *biofilms* (qv), or more widely in benthic marine sediments. Many *in vitro* studies continued to demonstrate the control exerted by biological compounds on the crystallization of various mineral species (Davies et al., 2003). Thanks to experiments that induced the precipitation of carbonate bodies in the presence of OM extracted from the Murchison CM2 meteorite, Reitner (2004) pointed out that abiotic OM may also induce organomineral formation.

Recently, Dupraz and Visscher (2005) proposed distinguishing carbonate organomineralization mediated

by crystal nucleation on recomposed EPS, as in the former examples documented by Défarge and Trichet (1995) in Polynesian microbialites, from carbonate precipitation following bacterial degradation of EPS: Bacterial degradation liberates EPS-bound ions such as Ca^{2+} , Mg^{2+} , or HCO_3^- , thus leading to outside solution supersaturation for Ca and Mg carbonates. The latter process is not considered by Dupraz and Visscher (2005) to be organomineralization *sensu* Trichet and Défarge (1995). However, sedimentary EPS may also concentrate ions independent of their living producers (Trichet and Défarge, 1995; Westall et al., 2000). In the case of carbonate precipitation induced by degradation of that sedimentary OM, since ion binding by EPS is a prerequisite for mineralization, this process should be considered a subcategory of organomineralization. The distinction between organomineralization induced by the liberation in solution of ions previously concentrated by sedimentary EPS and organomineralization involving a nucleating role of EPS corresponds to the distinction originally introduced by Trichet and Défarge (1995) between “organically induced” and “organically supported” organomineralization.

Geobiological consequences of organomineralization

Impact on present-day and past geological processes

Although difficult to evaluate, because it is frequently hard to distinguish from the direct role of biotic activity, and neglected by most geobiologists, the impact of organomineralization on sediment and soil formation is likely to be far from negligible. The works cited above (reviewed by Défarge et al., 2009) have already documented occurrences of organomineralization processes in the principal environments at the surface of the Earth, from deep cold water to shallow warm marine, through hyposaline to alkaline lakes, and terrestrial soils. They are involved in the formation of sedimentary calcareous buildups such as microbialites, mud mounds, and reefs (qv). Organomineral products include micrites, ooids, peloids, lithified cyanobacterial sheaths, worm housing tubes, animal tissues, and fecal pellets. The rapid authigenic phosphatization of tissues after death, leading to the preservation of soft-bodied fossils, likely involves matrix-mediated organomineralization processes (see Briggs, 2003, p. 292). The principal mineral species forming biominerals (Weiner and Dove, 2003) are also represented by organominerals: Ca carbonates and phosphates, and metal sulfides, oxides, and hydroxides; the silicification of EPS that occurs in biofilms independent of those of the microorganisms (Westall et al., 2000) may also be regarded as an organomineralization.

Défarge et al. (1996) showed that organomineralization processes are probably commonly involved in microbialite calcification; this was then confirmed in numerous cases (Défarge et al., 2009). The process of carbonate–fluorapatite precipitation mediated by dead

bacterial cells, proposed by Sanchez-Navas and Martin-Algarra (2001), in phosphate *stromatolites* (qv) that are representative of microbial structures frequently encountered in pelagic sediments from Mesozoic Alpine-Mediterranean paleomargins, may also be considered an organomineralization. The involvement of mineralizing OM remains the most plausible hypothesis for explaining the formation of magnesian calcite radial ooids composing numerous shallow marine carbonate sands (Morse et al., 2007). Neuweiler et al. (1999) provided evidence for the involvement of micrite organomineralization in the building of Lower Cretaceous mud mounds that are significant examples of calcareous buildups, possibly originating in the Neoproterozoic and common during the Phanerozoic. As EPS are essential components of microbial biofilms, which are widespread in nature and persistent throughout the history of life on the Earth (Westall et al., 2000), EPS-mediated organomineralization has probably been active at least since the appearance of living organisms, and may represent a geologically early process of mineral production coexisting with, or even preexisting, biomineralization.

Implications for astrobiological interpretations

Organominerals formed through the mediation of biologically derived OM may serve as *biosignatures* (qv) in the search for evidence of life in the geological rock record or on extraterrestrial bodies devoid of fossils or bioconstructions. Westall et al. (2000) stressed that mineralized EPS could be used as markers of the presence of bacteria in terrestrial or extraterrestrial materials. However, these biotic EPS need to be distinguished from potential prebiotic EPS that might have the same abilities for fossilization (Westall et al., 2000). Laboratory experiments by Reitner (2004) have shown that OM, likely abiotic, extracted from the Murchinson CM2 meteorite, was able to precipitate CC organominerals similar to those known from terrestrial microbial sediments. More generally, organic molecules were proved to be able to precipitate, in sterile conditions, Ca carbonate or phosphate mineral products resembling biologically induced minerals, in particular those interpreted as fossilized “*nan(n)obacteria*” (qv; Kirkland et al., 1999; Reitner, 2004; see other references in Défarge et al., 2009). Astrobiological studies for the search and the origin of life should keep in mind this spectrum of potential prebiotic, abiotic, or biologically derived organominerals in nature.

Potential engineering applications

Biomineralization processes have already inspired the design of new organic matrix-mediated materials by synthetic analogues of the matrices of natural biominerals (Davies et al., 2003). Such manufactured materials are artificial organominerals, although they can also be regarded, from a global geobiological perspective, as biominerals, because they are formed under direct biological, i.e., human, control. Similarly, organomineralization

sensu stricto might, in the future, inspire further engineering processes based on the precipitation of minerals or the extraction of ions from solutions in sterile conditions, applied, for example, to water and wastewater treatment, soil remediation and improvement, protection and restoration of building stones, etc.

Summary and perspectives

The direct role of life in the functioning and the evolution of our Planet is beginning to be fully recognized; witness is this encyclopedia. The geobiological impact of OM, however, which is in part included in the indirect role of biotic activity but may also be due to prebiotic or abiotic processes, is far from being equally well acknowledged and studied. Since the mineralizing role of OM has now been proved in various environments and geological periods, it should be searched for and identified in other case studies, in particular in carbonate formation that took place before the rise of calcareous organisms. While organomineralization research has mainly been devoted until now to EPS calcification, studies on organomineralization processes leading to the formation of other common biomineral species, such as phosphates, metal sulfides and oxihydroxides, or silica, should be continued, and the case of other species such as sulfates might be considered. The role of other types of sedimentary and soil OM also needs to be investigated. The possible involvement of abiotic OM in organomineral formation should be taken into account in astrobiological studies for the search of life on the primitive Earth and on extraterrestrial bodies. In addition to materials applications based on biomineralization processes, other studies might be devoted, in the future, to organomineralization-inspired engineering.

ORIGIN OF LIFE

Michael J. Russell
 California Institute of Technology, Pasadena, CA, USA

Definition

Life exploits free energy potentials to produce effluent at much reduced value. Put another way, it takes a low entropy feed, transforming it to high entropy waste. At the root or origin of the evolutionary tree as well as at the base of the food chain, life essentially draws down carbon dioxide by reducing it with hydrogen from a variety of sources, aided by a diversity of other aqueous solutes. Thus, life is a coded and organized entropy generator that can search and evolve to find further appropriate potential energies and materials.

Approaches to the origin of life

Origin of life theory has yet to reach a stage where it can take its place as the introductory chapter in textbooks in the life sciences. Why is this? Many researchers have concentrated on what life *is* rather than what life *does*, and have cast around for organic molecules that might have constituted the “building blocks” for the first cells – nucleic and amino acids, carbohydrates, and lipids. Thus comets (Ehrenfreund et al., 2006; see Chapter [Asteroid and Comet Impacts](#)), carbonaceous meteorites (Deamer, 1985), cosmic dust particles (Maurette, 1998), the products of lightning in a reduced atmosphere (Miller, 1953; Miller and Urey, 1959), and Fischer–Tropsch reactions within the Earth’s crust (Holm and Charlou, 2001) have all been appealed to in what may be called organogenic or heterogenic theories of origin. But research taking this tack has had little experimental success. Nor does it suggest an evolutionary link between such “prebiotic chemistry” and biochemistry. However, if instead of approaching life in terms of its constituents and where they might come from, but rather ask “what does life do,” it can be apprehended rather as a processor of energy and a generator of entropy, so inviting consideration of a thermodynamic, geochemical, and evolutionary context for the emergence of life. This approach has led to the autogenic theories for life’s origin, theories that view as

Definition

Life exploits free energy potentials to produce effluent at much reduced value. Put another way, it takes a low entropy feed, transforming it to high entropy waste. At the root or origin of the evolutionary tree as well as at the base of the food chain, life essentially draws down carbon dioxide by reducing it with hydrogen from a variety of sources, aided by a diversity of other aqueous solutes. Thus, life is a coded and organized entropy generator that can search and evolve to find further appropriate potential energies and materials.

Approaches to the origin of life

Origin of life theory has yet to reach a stage where it can take its place as the introductory chapter in textbooks in the life sciences. Why is this? Many researchers have concentrated on what life *is* rather than what life *does*, and have cast around for organic molecules that might have constituted the “building blocks” for the first cells – nucleic and amino acids, carbohydrates, and lipids. Thus comets (Ehrenfreund et al., 2006; see Chapter [Asteroid and Comet Impacts](#)), carbonaceous meteorites (Deamer, 1985), cosmic dust particles (Maurette, 1998), the products of lightning in a reduced atmosphere (Miller, 1953; Miller and Urey, 1959), and Fischer–Tropsch reactions within the Earth’s crust (Holm and Charlou, 2001) have all been appealed to in what may be called organogenic or heterogenic theories of origin. But research taking this tack has had little experimental success. Nor does it suggest an evolutionary link between such “prebiotic chemistry” and biochemistry. However, if instead of approaching life in terms of its constituents and where they might come from, but rather ask “what does life do,” it can be apprehended rather as a processor of energy and a generator of entropy, so inviting consideration of a thermodynamic, geochemical, and evolutionary context for the emergence of life. This approach has led to the autogenic theories for life’s origin, theories that view as

paramount consideration of the conditions upon the early Earth that drove life into being that see the emergence of life as a geological issue.

Therefore, the method applied in this entry is broadly evolutionary, autogenic, and mechanistic. We consider the onset of life as a natural and inevitable outcome of the well-established far-from-equilibrium conditions obtaining on our planet more than 4 billion years ago, especially the potential between hydrothermal hydrogen and atmospheric carbon dioxide. However, more reduced molecules bearing one carbon atom such as formate (CHOO^-), and methyl thiolate (CH_3S^-) may be required to get life going initially. Moreover, electrochemical energy is also seen to be needed in the form of the protonmotive force. Indeed, the first microbial vehicles were “hybrids,” driven into being by chemical potential and steep pH, redox, and temperature gradients across their membranes. So, first looking at what life does, we then investigate how life, as an energy and materials processor, may have begun. Only after metabolism’s engine is ticking over could genetic regulation and then replication emerge.

Life now

At root life takes molecules that are out of equilibrium at or near the surface of the Earth, reacts them together (i.e., processes or metabolizes them) within cells that can grow, reproduce, and evolve. None of this can happen without cell mortality and the excretion and disposal of relatively disordered waste products. In human metabolism the disequilibrium is between hydrogen released from foodstuffs (by dehydrogenases to nicotinamide dinucleotide (NAD to NADH)) and atmospheric oxygen (Williams and Ramsden, 2007). The waste products are carbon dioxide and water from energy production and the excreted disordered (higher entropy) organic molecules of lower energy rejected or degenerated during biosynthesis. But we live off others. At the base of the food chain are organisms that directly exploit the disequilibrium between hydrogen released from water in some manner, and from the carbon dioxide gleaned from the atmosphere. The obvious examples of the food-chain’s base are the plants and the cyanobacteria (see Chapter *Cyanobacteria*). They split hydrogen from water into four protons and four electrons during oxygenic photosynthesis using, amongst other mechanisms, a complex enzyme known as photosystem 2 (PS2) (Blankenship, 2002); oxygen is released as waste:

The protons and electrons are then “fed” to the carbon dioxide, which with further enzymatic assistance, is thereby reduced to cellular carbon and some waste water:

However, there is a still more basic metabolism whereby prokaryotes use the hydrogen emanating naturally from hot springs in a geochemical, rather than a photosynthetic, reaction (Spear et al., 2005; see Chapter *Hydrogen*). The hydrogen is released during hydrothermal convection as the water oxidizes the ferrous iron in minerals such as fayalite olivine (Fe_2SiO_4) in the Earth’s crust:

This hydrogen can reduce carbon dioxide in certain prokaryotes through the involvement of nicotinamide dinucleotide (NAD), chemiosmosis, iron-nickel hydrogenases, and iron-sulfur proteins (Daniel and Danson, 1995; Volbeda and Fontecilla-Camps, 2005a; Williams and Ramsden, 2007; McGlynn et al., 2009; see Chapters *Hydrothermal Environments*, *Marine* and *Nickel*, *Biology*). In such cases the carbon wastes are either acetic acid as in the homoacetogens (and see Chapter *Acetogens*):

or methane as in the methanogens (see Chapter *Methane*, *Origin*):

Based on the uniformitarian principle (that the present is the key to the past) we expect today’s food chain to recapitulate the evolutionary tree of metabolic pathways, thereby giving us a strong indication of what the earliest biochemistry was like. From this knowledge we might enquire whether there is a match between such a biochemical expectation and the very slow aqueous geochemical reactions arising from the initial conditions on our planet four or more billion years ago – reactions that could have been quickened through the emergence of life. A positive response to the question has led to a hydrothermal theory of the origin of life that at first sight seems to lie strictly in the autogenic camp – a theory that expects that the first metabolism was based on acetogenesis and methanogenesis (see Chapters *Acetogens* and *Methane*, *Origin*).

Autogenic theory

The class of theory that invokes the simplest of components such as carbon dioxide and ammonia to explain the emergence of life was first termed “autogenic” by Haeckel (1870, p. 302; 1892, p. 414). Mereschowsky (1910, p. 360), Harvey (1924), and Corliss et al. (1981) thought the same way. Because *appropriate* organic molecules were not to be had on the early Earth, an origin of life based on minerals and their component clusters was generally assumed (Leduc, 1911; Goldschmidt, 1952; Hall et al., 1971). A modern autogenic version of the theory considers the early Earth as having surface geochemistries that fed into the overall reactions as identified in Equations 2, 4, or 5 (Shock 1992; Russell and Arndt, 2005; Russell and Hall, 2006). Of these, what is the most

likely first reaction and thereby the most plausible pathway to life? Obviously, if hydrogen were to have been provided freely to emergent life, the putative first organism is hardly likely to have managed (or bothered) to develop such a complicated system of accessing it from water near the turbulent ocean's surface in the face of destructive ultraviolet radiation. That leaves reaction 4 as the likely energizer of life and source substrate for its structures. Reaction 5 could only supply energy. However, the generation of the intermediate radicals formyl ($-\text{HCO}$), methenyl ($-\text{CH}^+$), methylene ($-\text{CH}_2$), and methyl ($-\text{CH}_3$) in both reactions 4 and 5 are kinetically (Shock, 1990) and, in the early steps, thermodynamically (Maden, 2000) challenged, requiring both catalysis and energy for their resolution, (Figure 1). Yet these intermediates are themselves points of departure for biosynthesis (Maden, 2000). The kinetic barrier is higher for methane synthesis because the addition of a carbon-bearing radical ($-\text{COX}$) to a methyl ($-\text{CH}_3$) group to produce acetate ($\text{H}_3\text{C}-\text{COO}^-$) faces less of an obstacle than does the addition of a hydride (H^-) to make methane (CH_4) (Maden, 2000). Thus a pathway to acetate was probably the first to develop (Fuchs, 1989; Crabtree, 1997). Exploiting such a metabolism is the task of the acetogenic bacteria via what is known as the acetyl coenzyme-A pathway (Russell and Martin, 2004; see Chapter *Acetogens*):

However, the path to methane production has much in common with the acetogenic pathway and could not have been far behind in evolutionary terms (Martin and Russell, 2007). Nevertheless, the microbes that excrete methane are so different from the acetogens that they have been assigned to a different domain of life, viz., the archaea (Woese et al., 1990, see Chapter *Archaea*). In this entry we will limit ourselves to an explication of the emergence of autotrophic acetogenesis and methanogenesis as biochemistry's first essay into processing chemical and electrochemical energy and generating cellular carbon. Given these qualifications, is there a likely context for where these reactions might have been promoted on the early Earth? To answer this we need to take a look at the conditions on our planet around 4 billion years ago.

Conditions at ~4 Ga

Presently taking up ~70% of the planet's surface, the Earth 4 billion years ago was probably completely covered with water. Radiogenic, gravitational, and tidal heat rendered any continental massifs differentiated by then so hot as to be too pliable and plastic to break the surface of the Hadean Ocean (Russell and Arndt, 2005). Subject to gales and hurricanes and given to high tides on a planet where the day lasted a few hours, this ocean was in a state of constant turmoil. There was certainly no place near the UV-saturated chaotic surface where organic molecules had the peace to organize into anything more complex than small ephemeral slicks. And the atmosphere was dominated by CO_2 , mainly from a myriad of highly active volcanoes derived from the Earth's mantle that had lost its native iron through rapid gravitation to the Earth's core (Wood et al., 1990; Delano, 2001; Boyet and Carlson, 2005; Wood and Halliday, 2005). Also exhaled from volcanoes, pyrophosphate rained into the ocean (Yamagata et al., 1991; Hagan et al., 2007). Any reduced carbon molecules were photo-oxidized to more CO_2 . The carbonic ocean was acidic (pH 5–6) (Macleod et al., 1994; Lowell and Keller, 2003; Halevy et al., 2007). Acidic too were (and are) the 400°C springs exhaling at ocean spreading centers and above mantle plumes (see Chapter *Hydrothermal Environments, Marine*). Because the Fe: H_2S ratio was $\gg 1$ in these very hot fluids emanating into the reservoir of that acidic ocean (Kump and Seyfried, 2005; Konhauser et al., 2009). These metals (e.g., Fe, Mn, Zn, Ni, Co, V, Mo, and W) are just the ones that contribute to metalloenzymes, particularly important to the autotrophic prokaryotes (Cody, 2004; Volbeda and Fontecilla-Camps 2006; McGlynn et al., 2009; see Chapter *Metalloenzymes*).

In contrast to the acidic hot springs, a large number of alkaline springs would have emanated at some distance from the oceanic spreading centers, similar in many ways to those found today at Lost City, 15 km from the

Origin of Life, Figure 1 Free-energy profiles of acetogenic and methanogenic reduction pathways (the reverse eastern branch of the acetyl coenzyme-A pathway, Ragsdale, 1997), compared to the geochemical pathway (cf. Seewald et al., 2006). Note how adenosine triphosphate (ATP) or an ionic gradient are required to drive early stages of CO_2 reduction in the acetogens and methanogens respectively. Without such a boost of energy the geochemical reduction of CO_2 to formaldehyde is minor and the abiotic production of acetate or methane is extremely slow. Life emerged as a processor to quicken the reactions which are exergonic overall. (Redrawn and recast from Maden, 2000.)

Mid-Atlantic Ridge (Kelley et al., 2001). The Lost City fluids exhale at moderate temperatures ($\leq 90^\circ\text{C}$), are alkaline ($\text{pH} \leq 11$) and contain up to 15 mmol/kg of dissolved hydrogen (Kelley et al., 2001; Martin et al., 2008; and see Macleod et al., 1994). They have exhaled without a break for at least 35,000 years (Früh-Green et al., 2003). Apart from hydrogen, other reduced entities likely delivered by moderate temperature alkaline springs on the early Earth were formate (HCOO^-), ammonia (NH_3), hydrosulfide (HS^-), methanol (CH_3OH), methane thiol (CH_3S^-), and methane (CH_4) (Schulte and Shock, 1995; Russell and Hall, 1997; Shock et al., 1998; McCollom and Seewald, 2003). Metals of potential biochemical interest carried in these moderate temperature fluids are molybdenum and tungsten. These solutes from alkaline springs – when juxtaposed with the carbon dioxide, transition metals and protons in the Hadean Ocean – provide all the basic nutrient and appropriate energy requirements for chemolithotrophic life as outlined below (Figure 2).

The theory of the onset of life at an alkaline hydrothermal vent

The hydrogenations of atmospheric carbon dioxide on the early Earth to either acetate or methane (Equations 4 and 5), as well as of the organic by-products of these reactions (and their intermediates) that comprise living cells, are faced with both thermodynamic and kinetic barriers (Figure 1). This is the theoretical challenge to an evolutionary theory of the emergence of life. To conquer kinetic barriers, there must be common naturally occurring

minerals that not only have the appropriate catalytic propensities but also are likely to be easily sequestered by organic molecules that they might evolve to protoenzymes. To override the thermodynamic barriers at the early stages of reduction (Figure 1), extra electrochemical energy is required to drive reactions 4 and 5 toward completion; energy supplied through chemiosmosis and the protonmotive force as alluded to below (Mitchell, 1967, 1979; Kell, 1988).

A plausible context where the necessary thermodynamic/electrochemical drive and natural catalysts comes into play is at a long-lasting hydrothermal vent. Here such alkaline solutions feed springs of constant temperature ($\leq 100^\circ\text{C}$) and $\text{pH} (\leq 11)$ that exhale at a distance from ocean-floor spreading centers into a somewhat acidic ancient ocean (Shock, 1992; Russell et al., 1994) (Figure 2). As this alkaline solution titrates with the metal-bearing acidulous ocean, porous and semi-permeable hydrothermal mounds form through precipitation of the metals as sulfides, carbonates, clays, and oxyhydroxides (green and white rust) on the ocean floor. Evidence for the porous nature of mound structure derives from modern examples (Marteinsson et al., 2001; Kelley et al., 2005) as well as from 350 million year old fossil representatives at mineral deposits in Ireland. These latter structures formed from similar titrations to those defined above, though where the pH of the two solutions was inverted (Figure 3) (Russell and Hall, 1997). Like these

Origin of Life, Figure 2 A submarine mound with the properties of a natural self-restoring flow reactor and fractionation column growing on the Hadean ocean floor above an alkaline spring. (After Russell and Martin, 2004.)

Origin of Life, Figure 3 Polished cross section of iron sulfide botryoids (bubbles or compartments) from the Tynagh mineral deposit in Ireland. These structures inspired the idea that the first compartments involved in the emergence of life were of comparable structure. It should be noted that the sulfide comprising what is now pyrite (FeS_2) in these 350 million year old submarine deposits was derived through bacterial sulfate reduction that took place in somewhat alkaline and saline seawater while the ferrous iron was contributed by exhaling acidic hydrothermal solutions. On the early Earth the sulfide would have been carried in the alkaline solution in some springs as abiotic bisulfide (HS^-), whereas the ferrous iron would have been contributed from the acidulous Hadean ocean. On mixing of the two solutions, nickel bearing mackinawite ($\text{Fe}(\text{Ni})\text{S}$) and greigite (Fe_3NiS_8) would have precipitated to contribute to inorganic barriers or membranes at their interface. (From Russell et al., 1994.)

morphologies, the growing surface of Hadean mounds probably comprised bubbles and compartments made of iron sulfide (FeS) and hydroxide gels with subordinate nickel, wherever the alkaline solutions were particularly sulfidic. Microcavities within initially colloidal iron monosulfide and hydroxide precipitates acted as the original chemically and electrochemically driven catalytic culture chambers for early metabolism and embryonic life (Russell et al., 1994). Thus the hydrothermal mound takes on the attributes of a continually renewed catalytic flow reactor and fractionation column, fed by hydrogen from within, and protons from without (Russell and Hall, 1997; Stone and Goldstein, 2004; Martin and Russell, 2007). Here, fresh catalytic iron sulfide and iron hydroxide nanocrystalline surfaces are continually offered as catalytic reaction sites between hydrogen (separated into electrons and protons) plus formate in the hydrothermal solution, and the carbon dioxide dissolved in the ancient ocean. The sulfides are mainly mackinawite (FeS) and greigite (Fe₃S₄) (see Chapter *Iron Sulfide Formation*) – sulfides which accommodate nickel, an effective and common catalyst. The atomic lattices of these sulfides have affinities with those of the active centers of enzymes involved in the acetyl coenzyme-A pathway mentioned above (Figure 4) (see Chapter *Metalloenzymes*).

Mackinawite (FeS) comprises rhomboids of FeSMS (where M = Fe, Ni or Co and S = sulfur) whereas in the

rather more oxidized greigite [NiFe₅S₈] these rhombs associate to form Fe₄S₄ cuboids with a distal iron or nickel atom ligated through two sulfur atoms (Figure 4a). Further oxidation (sulfidation) to pyrite (FeS₂) is prevented by formaldehyde (HCHO) (Rickard et al., 2001), significant because a formyl (–CHO) group is an early intermediate produced along the acetyl coenzyme-A pathway (Figure 1) (see Chapter *Acetogens*). The mackinawite rhomboids have a similar topology to the active centers of Fe–Fe and Fe–Ni hydrogenases involved in acetogenesis and methanogenesis (McGlynn et al., 2009). The greigite structure (Figure 4a), by contrast, is topologically similar to that of the [4Fe–4S]^{0/+} centers of the ferredoxins (proteins that act as electron transfer agents) (Figure 4b); to the active center of carbon monoxide dehydrogenase (CODH) (e.g., [Fe₄S₄]S–Ni or [Fe₃NiS₄]Fe) (Figure 4c) where CO₂ is reduced to CO; and to the [Fe₄S₄]cys–Ni–cys₂–Ni] center of acetyl coenzyme-A synthase (ACS) where the acetyl group (CH₃CO[–]) is assembled (Figure 4d) (Vaughan and Ridout, 1971; Rickard and Luther, 2007; Dobbek et al., 2001; Drennan et al., 2001; Volbeda and Fontecilla-Camps, 2005a, b). (An animation of the mechanism by which an Fe–Ni hydrogenase, with the involvement of two 4Fe–4S centers and a 3Fe–4S center, splits hydrogen into 2 protons and 2 electrons, is beautifully illustrated at <http://www.kcl.ac.uk/ip/richardcammack/H2/animation/movie1.html>).

Origin of Life, Figure 4 The molecular structure of the mineral greigite (a) is very similar to that of the thiocubane unit (b) of the ferredoxin protein, as well as to the cuboidal complex (c) in the active site of the enzyme acetyl-CoA synthase/carbon monoxide dehydrogenase (shown in schematic form). The X-ray crystal structure (d) for the so-called A cluster of the latter confirms this similarity. Atoms are colored as follows: iron, red; sulfur, yellow; nickel, green; carbon, gray; nitrogen, blue. R signifies links through sulfur to the remainder of the protein. Part (d) is modified from Darnault et al. (2003) (and see Fontecilla-Camps and Ragsdale, 1999). (From Russell 2006, with permission.)

Is there experimental evidence to favor catalytic involvement of such iron-nickel sulfides or of nickel in the synthesis of acetate as we might expect from Equation 4 and in the conditions outlined above? No. The stumbling block appears to be the reduction of carbon dioxide to carbon monoxide in the analogy with a reversed “eastern branch” of the acetyl coenzyme-A pathway (see Ragsdale, 1997) (Figure 1). However, though yields are low, Heinen and Lauwers (1996) have reduced carbon dioxide to methyl sulfide (CH_3S^-) (in a short-cut through a reversed “western branch”) irreversibly from hydrogen sulfide and carbon dioxide in acidic conditions in the presence of ferrous sulfide where pyrite was apparently also produced at the liquid–vapor boundary:

Though a much simpler molecule, methylsulfide ($\text{CH}_3 \cdot \text{SH}$) is comparable to the thiol acetyl-coenzyme-A ($\text{Co-A} \cdot \text{SH}$) that expedites the leaving of activated acetate from ACS. In theory methane thiol activities would rise a 1000-fold when generated from H_2 and CO (rather than CO_2) in the crust or the hydrothermal mound (Schulte and Rogers, 2004).

The production of pyrite in the Heinen–Lauwers experiment is an expectation of the “Pyrite-Pulled Theory” of Wächtershäuser (1988a,b) and we now explore some experiments based on his hypothesis. Wächtershäuser, and his collaborator Claudia Huber, did synthesize the energy-rich methyl thioacetate ($\text{CH}_3 \cdot \text{COSCH}_3$) from the methane thiol (as produced by Heinen and Lauwers, 1996). However, apart from the thiol, they also used carbon monoxide gas rather than the much more stable dioxide (Huber and Wächtershäuser, 1997):

In a further departure from the biochemical pathway it should be noted that carbon monoxide is not stable in alkaline solution. However, a single carbonyl radical ($=\text{C}=\text{O}$) could perhaps be produced locally at each nickel site in greigite, dissociated from hydrothermal formate in the mound in a reaction driven to the right by the high CO_2 and H_2 partial pressures obtaining at an alkaline vent:

However, the Huber–Wächtershäuser reaction (8) is comparable to the addition of a carbonyl group to the methyl sulfide facilitated by acetyl coenzyme-A synthase (ACS) (Figure 4d) (Crabtree, 1997; Schink, 1997; Amend and Shock, 2001). The synthesis works best when catalyzed by NiS in acidic or alkaline conditions or with nickel sulfate in alkaline conditions – a result to be expected from knowledge of the biochemical reaction, the hydrothermal context, and also the role of nickel in the active site of ACS (Figure 4d) (Ragsdale, 2004). As we shall see, this energetic thioester ($\text{CH}_3 \cdot \text{COSCH}_3$) could be variously

carboxylated, condensed, aminated, or used to make pyrophosphate. In the latter case, acetate is the waste product as it is of the acetogens. We turn now to energy requirements for further biosynthetic reactions that are also thermodynamically uphill. Where might this energy have come from at the emergence of life?

Pyrophosphate

Life requires measures whereby energy can be stored. Now it employs various pyrophosphates for the job, notably adenosine triphosphate (ATP) produced either from substrate reactions (Gottschalk, 1985) or via the protonmotive force (Mitchell, 1967, 1979). ATP is too complex a molecule to be considered a geochemical product. It must be a product of early biological evolution. Thus we need to consider a precursor. One possibility is inorganic pyrophosphate (Westheimer, 1987; Baltscheffsky et al., 1999). And, seeing that acetate is one likely early product of emergent biochemistry, the first organic phosphate may have been acetyl phosphate ($\text{CH}_3 \cdot \text{CO} \cdot \text{PO}_4^{2-}$), perhaps produced by substrate phosphorylation of the acetyl thioester (from Equation 8) (de Duve, 1991):

Reacting this acetyl phosphate product with inorganic phosphate (HPO_4^{2-}) in the presence of Fe^{II} minerals, de Zwart et al. (2004) have generated pyrophosphate with a yield of 25% at $\sim 40^\circ\text{C}$,

comparable to the way ATP is produced by the phosphorylation of adenosine diphosphate (ADP) in the acetyl coenzyme-A pathway. FeS was found to strongly retard hydrolysis of, and thus preserve, the pyrophosphate (de Zwart et al., 2004). Either the acetyl phosphate or the resulting pyrophosphate (PPi) (Equation 10) could have provided a proportion of the energy to drive hydrogenations at the formate-to-formyl step along the acetyl coenzyme-A pathway (for the acetogens in Figure 1) (Romero et al., 1991; Baltscheffsky et al., 1999). It might also have polymerized amino acids. For example, an overall condensation of glycine ($^+\text{H}_3\text{N} \cdot \text{CH}_2 \cdot \text{COO}^-$) with pyrophosphate on a mineral surface could theoretically produce diglycine:

However, this amount of pyrophosphate is a small proportion of the energy required for biosynthesis (Amend and Shock, 2001; Martin and Russell, 2007). The extra energy

could only be supplied by protons, via the protonmotive force as detailed next.

At the origin of life the iron sulfide/hydroxide precipitates do more than merely provide catalytic surfaces. They also act as compartment walls, tending to trap organic products that become involved in further reactions, while permitting the transfer of anions across the membrane driven by proton flow (Russell et al., 1994). This natural protonmotive force, a consequence of the pH gradient operating across these inorganic membranes, is also the energy with the potential to drive pyrophosphate synthesis and thereby further hydrogenations and condensations (Mitchell, 1979). If the fluid inside the compartments has a pH of ~10 and the ocean has a pH of ~5, then the “protonic” potential approximates 300 mV; enough geochemical energy to have driven metabolism on early Earth (Russell et al., 2003). That the pH-dependent boundary between the mono- and di-phosphate fields intersects the (primarily) Eh-dependent iron sulfide fields demonstrates how “proticity” (a proton current) could have driven the condensation of inorganic phosphate (Pi) to pyrophosphate (PPi) (Figure 5). So in theory the proton gradient could have been simply coupled through the membrane to this dehydration or condensation of monophosphate on nanocrystalline surfaces within the inorganic membrane (Russell and Hall, 2006):

In biochemical energetics the process is known as “oxidative phosphorylation,” a reference to the fact that protons in living systems are initially driven to the outside of the membrane (to maintain charge balance with outflowing electrons to an acceptor) before returning to recharge the

Origin of Life, Figure 5 Dependence of the formation of phenylalanine dipeptide on pH (and see Huber and Wächtershäuser, 1998, 2003) for comparable results. (From Leman et al., 2004, supporting on-line material www.sciencemag.org/cgi/content/full/1101400/DC1, with permission.)

phosphate (Mitchell, 1967). The protonmotive force is the power behind metabolism and is therefore indispensable to life. So the fact that this ambient force is a feature of the redox and acid-to-alkaline interface separated by a semiconducting inorganic membrane suggests that the emergence of life was driven by similar energetic gradients as obtain in modern living systems. Nevertheless, the “ATPase” responsible for the conversion in today’s organisms is a complex rotating turbo-motor driven by a flow of protons from the membrane’s exterior (Elston et al., 1998). We assume that phosphate adhering to the mineral surfaces comprising the inorganic membrane was sequestered by short chains of amino acids (peptides) in a prototype of the phosphate-binding loop (the so-called P-loop) to form a pyrophosphatase as explained in a later section (Milner-White and Russell, 2005, 2008). This eventually evolved to the relatively simple, static H^+ -pyrophosphatase (Baltscheffsky et al., 1999; Hirono et al., 2007). That the amino acids and the subsequent heterochiral peptides required for such sequestering can be generated in an alkaline hydrothermal environment at moderate temperatures has been demonstrated by Wächtershäuser and his collaborators (Huber and Wächtershäuser, 1998; Huber et al., 2003).

Amino acid and peptide synthesis

Huber and Wächtershäuser (2003) have successfully aminated α -keto acids (like the pyruvate synthesized hydrothermally by Cody et al., 2000), but only in alkaline conditions. Amino acid yields are highest around pH 9, close to the pK_a of ammonium at 9.25 (Huber and Wächtershäuser, 2003). In these experiments $\text{Fe}(\text{OH})_2$ (“white rust”; a constituent, along with FeS , of the precipitate membranes) was shown to be just as effective a catalyst as iron monosulfide.

Similarly, alkaline (pH ~ 9) conditions are required in the condensation of amino acids to short peptides, though in these experiments an iron-nickel sulfide slurry was used as catalyst and carbon monoxide employed as condensing agent (Huber and Wächtershäuser, 1998, 2003). Of significance to the debate on the origin of chirality, lepto-tyrosine was found to racemize on condensation to give alternating L and D residues (Huber and Wächtershäuser, 1998, 2003). Leman et al. (2004) also condensed amino acids at similar alkaline pH, though using carbonyl sulfide in place of CO (Figure 5). The formation of peptides heralded a new stage in complexity at the emergence of life as we shall see. However, before this stage we must consider how organic molecules produced in these kinds of reactions might have been concentrated in the inorganic compartments comprising the mound.

Organic concentration in inorganic compartments

At the origin of life the iron-nickel precipitates did more than merely provide catalytic surfaces. They also acted as compartment walls, tending to trap organic products that became involved in further reactions. Yet they likely

permitted the transfer of anions across the membrane driven by the flow of protons from the acidulous Hadean Ocean through to the alkaline interior (Russell et al., 1994). And the protons had the potential to drive the condensation of phosphate to pyrophosphate; an example of ambient chemiosmosis. Evidence that such compartment walls could have existed in such an environment is afforded by what appear to be hollow but contiguous iron sulfide bubbles found at the 350 million year old Tynagh metal sulfide deposit in Ireland (Russell and Hall, 1997) (Figure 3). This ephemeral trapping of the rising hydrothermal solution, and its interfacing with the carbonic ocean across the inorganic membrane, also placed it at the mercy of physical as well as chemical gradients in an environment that could cause crowding of product (cf. Ellis, 2001).

Concentration through thermal diffusion

Quantities of the organic intermediates and further products of geochemical acetogenesis and methanogenesis, such as amino acids and short peptides, will tend to be trapped in solution within the inorganic compartments comprising the hydrothermal mound. Noting that the hydrothermal mound could act as an affinity column, some of the organic anions will be concentrated on the compartment wall. However, Braun and Libchaber (2004) demonstrate *in vitro* how thermophoresis (thermal diffusion) accumulates charged polymers, with the potential to drive them to high concentrations in the cooler, stagnant portions of individual reaction microchambers. Such a process would be most effective on the outer margins of a hydrothermal mound where the temperature gradient was high and ranged between 50 and 100°C; just the kind of gradient to be expected in the envisaged mounds growing at off-ridge hydrothermal springs and seepages. Such “crowding” of newly generated macromolecules would decrease the activity of water and thence inhibit hydrolysis and thus further enhance the assembly of oligomeric structures and their subsequent folding into functional peptides. It would also quicken the rates of reaction along metabolic pathways; a prelude to an organic takeover from mineral catalysis and compartmentation.

An organic takeover

Protoenzymes and coenzymes

The consanguinity between the first structural and catalytic sulfide precipitates (Figure 4) and pyrophosphate with early enzymes (Russell and Hall, 1997; Beinert et al., 1997; Baymann et al., 2003; McGlynn et al., 2009) suggests that these structures were sequestered by the short heterochiral peptides similar to those produced in the Huber–Wächtershäuser experiments. Eck and Dayhoff (1966), pointing to the likely ubiquity and catalytic propensity of FeS on the early Earth, made the suggestion that the ferredoxins had the longest pedigree of all enzymes. Even before genetic control similar structures

Origin of Life, Figure 6 Ball and stick pictures showing early nests of short heterochiral peptides. The inorganic moieties are ligated through hydrogen bonds to the nitrogen atoms in the main chain of the polypeptides: *Left*, $[\text{Fe}_3\text{S}_4](\text{RS})_4^{3-}/4^-$ bound to a heterochiral peptide nest (cf. the ferredoxin in Figure 4b); *Right*, phosphate bound to a peptide nest (cf. the P- or phosphate loop). [carbon, green; oxygen, red; iron, rust; nitrogen blue; phosphorus, orange; sulfur, yellow]. (From Milner-White and Russell 2008, with permission.)

may have formed spontaneously. For example, Bonomi et al. (1985) demonstrate the synthesis in water of iron sulfide clusters ligated to organic sulfides (e.g., thioethanol) to produce $[\text{Fe}_4\text{S}_4](\text{RS})_4^{2-}$ anions in aqueous solution. Mildly hydrophobic short peptides are attracted to these anionic complexes by virtue of the δ^+ charge on the amino group nitrogen atoms along the backbone of the peptide chain ($\text{N}^{\delta+} \text{H} \cdot \text{CH}_2 \cdot \text{CO}^{\delta-} \cdot \text{N}^{\delta+} \text{H} \cdot \text{CH}_2 \cdot \text{CO}^{\delta-}$). These bend and bow to satisfy the negatively charged clusters (Figure 6). Cosseted in such “peptide nests,” the active centers (“eggs”) would be partially protected from dissolution, nucleation, and crystallization. Also, given the high surface-to-volume ratio of the clusters, they would remain highly active, yet spaced at distances appropriate for electron tunneling that allowed multi-electron bond-forming and breaking catalysis at high rates (Milner-White and Russell, 2005, 2008; Moser et al., 2006; Hengeveld and Fedonkin, 2007).

While these protoferredoxins were involved in electron transfer, phosphate anions were required for the storage of energy used in biosynthesis. These anions could also be sequestered by the backbones of short peptides. Indeed, a similar structure – the P-loop – is still a protein-motif of the phosphatases in prokaryotes to this day, the conformation now permitted by the one or more of the non-chiral amino acid glycine residues featured in the structure (Milner-White and Russell, 2008) (Figure 6). The “ready-made” aspect of these catalytically active molecular clusters is at one with the view that there was an evolutionary continuum between hydrothermal chemistry on the early Earth and emergent biochemistry (Russell and Hall, 1997; Martin and Russell, 2007). However, the short peptides may have had another important role as we see below.

Amyloid as the first organic membrane

Although FeS-bounded “cells” are plausible candidates for the hatcheries of life, they are flimsy, leaky, and poor

insulators. In the absence of lipids, which appear to be a late microbiological invention (Koga et al., 1998), peptidic membranes and walls to protocells offer several advantages to a metabolizing system before the advent of a genetic control. For example, sticky amyloid peptide would have made protective insulating layers and thus may have constituted the first organic membranes and cell walls (Zhang et al., 1993; Chernoff, 2004; Carny and Gazit, 2005; Liu et al., 2008). Some amyloid strands are like the nests described above but are flatter (Milner-White and Russell, 2008). Once concentrated by thermophoresis to the exclusion of inorganic anions, peptides will bond with each other. The δ^- of the carbonyl oxygens of one peptide ($\cdot\text{N}^{\delta+}\text{H}\cdot\text{CH}_2\cdot\text{CO}^{\delta-}\cdot\text{N}^{\delta+}\text{H}\cdot\text{CH}_2\cdot\text{CO}^{\delta-}\cdot$) will interact electrostatically with the δ^+ of the nitrogen atoms along the backbone of the next. Thus sheets of amyloid are formed that rapidly aggregate to blocks. Composites of this type of amyloid might coat the inside of the iron sulfide compartments, and eventually take over from it entirely. However, the amyloid is not limited to merely acting as an inert and impermeable membrane. In cases where the amyloid blocks are juxtaposed such that their charges are the same, then the natural repulsion between, for example the δ^- of the carbonyl groups will generate a natural channel that could allow transmission of particular ions, e.g., H^+ and K^+ (Milner-White and Russell, 2008).

Because this type of amyloid is composed of alpha-sheet, it could truss clusters such as the $[\text{Fe}_4\text{S}_4][\text{RS}]_4^{2-}$ anionic centers within its structure as stabilizers and electron transfer agents (Figure 6). It could also sequester the phosphates and pyrophosphates $[\text{HP}_2\text{O}_7^{3-}]$ required for early biosynthesis. Moreover, as glycine comprised much of the first peptide (Hennet et al., 2001), tetraglycines could sequester single atoms of Ni, Co and other transition elements as reduction- and group-transfer enzymes, as do the tetrapyrroles in acetogenesis and methanogenesis (Eschenmoser, 1988; Thauer, 1998; Milner-White and Russell, 2008).

The emergence of the code

We have seen how the mound plausibly acts as the organic-molecule factory, i.e., as a compartmentalized flow reactor. Acetate, amino acids, and short peptides are synthesized in it. And natural iron-nickel sulfide catalysts, and phosphate condensing agents, are sequestered by short peptides to produce protoenzymes and coenzymes. The inorganic, compartmentalizing membrane may then be superseded by a peptidic/amyloid membrane. The hydrothermal feed of hydrogen, formate, ammonia, and sulfide continues without interruption and meets the carbon dioxide, ferrous iron and phosphate in the acidic Hadean Ocean. Unlimited energy in the form of hydrothermal hydrogen and of protons and electron acceptors in the ocean guarantees continual synthesis of

organic molecules. What we do not have is replication – a reliable regulator, translation, or memory – we do not have genes.

Yet at first no special place in this decentralized “unintentional” world should be given to RNA beyond it being metabolically and homeostatically useful and thereby a surviving molecule (Hengeveld and Fedonkin, 2007). Prior to the involvement of nucleic acids in RNA and DNA, the nucleosides had metabolic roles, for example as pyrophosphate-bearing molecules like ATP and GTP (White, 1976). In time, and as polymers, they took over as information molecules, helping to regulate metabolic interactions, replicating and coding for propagation. But how were the ribose bases first assembled?

Although an unstable entity, once formed RNA would be less mutable when secured upon a mineral surface, especially in the presence of highly reduced fluids. Nevertheless, the synthesis of nucleic acids, composed of a phosphorylated ribose sugar attached to one of four possible bases, is a problem more daunting than that of the amino and carboxylic acids. As a start we note that pyrophosphate, introduced through volcanoes to the early oceans, remained in solution in the relatively acidic ocean, although some would have been precipitated as vivianite ($\text{Fe}_2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$) and as a condensed pyrophosphate on mixing with moderate temperature alkaline fluids at the hydrothermal mound (Rouse et al., 1988; Yamagata et al., 1991; Russell and Hall, 1997; de Zwart et al., 2004; Hagan et al., 2007). An explanation of how RNA bases were first synthesized in the mound still escapes us. One possibility is that they were constructed upon mineral surfaces in a sequence not very different from the way they are generated in the cell, for example with the simple entities; aspartate, glutamine, glycine, formyl phosphate, ammonia, and carbon dioxide (Martin and Russell, 2007). The synthesis of ribose phosphate, the particular pentose sugar attached to the bases, is also difficult to understand but may have been produced from phosphoenolpyruvate, itself a product of the acetyl coenzyme-A pathway (Martin and Russell, 2007). Anyway, apart from the easily synthesized adenine, only small concentrations of the rest were needed because, as we shall see, RNA polymers were the “moulds” that may have produced a myriad of peptide “casts.”

Emergence of the RNA world

In living cells amino acids are sequenced and polymerized in a process centered on the ribosome, composed essentially of RNA that ratchets along messenger RNA (Ban et al., 2000). Such a complex process must have evolved from a simpler system. Just what this was is the most challenging problem facing origin of life research. What follows is a speculative attempt to point to research directions. Neglecting their side chains, amino acids comprise a negatively charged carboxyl group ($-\text{COO}^-$) and a positively charged amino group ($-\text{NH}_3^+$). Amino acids

are polymerized by the loss of the constituents of water, OH^- from the carboxyl of one amino acid and of H^+ from the next. Though experiments show that condensation may be driven by carbon monoxide, carbonyl sulfide, or by drying (Ferris et al., 1996; Huber and Wächtershäuser, 1998; Huber et al., 2003; Leman et al., 2004), pyrophosphate phosphorylation is a possibility more in line with an alkaline hydrothermal origin though in conditions where water activity was low (see Baltscheffsky et al., 1999; Baaske et al., 2007) (Equation 18). While this may have happened in the first membranes, a polymerase would have been more efficient.

Woese (1967) suggested that genetic information was first transferred to protein sequences directly by selection through a somewhat indiscriminate “codon-amino acid pairing.” This relied upon the affinity between the shape and charge of the codon (a triplet of three nucleic acids) with the shape and charge of the amino acid and especially of its side chain (Woese, 1967, pp. 174–175). Thus, what is known as the peptidyl transferase reaction of an RNA molecule might have evolved via direct translation on a protoribosome. Although somewhat indiscriminate, triplets of side chains of RNA facilitating polymerization tended to favor particular amino acid side chains to the polymerizing amino acid sequence. Mellersh (1993) emphasized that RNA triplets offered a cleft-like (tridentate) conformation to attract amino acids in this way when adhering to a solid phase such as clay. The rows of RNA triplets then gripped and juxtaposed amino acid monomers in such a way as to offer the carboxyl group of one amino acid to the amino group of the next for bonding (Mellersh, 1993). At the same time the affinity between the clefts of RNA and the side chains of the amino acids would happen to effect a crude selection by codon-amino acid pairing as envisaged by Woese (1967). For example, clefts in which uracil was the central base would tend to attract only amino acids with hydrophobic side chains such as that of methionine ($\text{NH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{SH} \cdot \text{CH}_3 \cdot \text{COOH}$), while those in which adenine was central would show affinity for the hydrophilic charged, or polar, amino acids.

Concentrated by thermal diffusion, amino and nucleic acids occupied the cooler zones within the mineral and/or amyloid compartments (Braun and Libchaber, 2004). Where water activity was low, RNAs on the surface of nanocrystals may themselves have replicated by Watson–Crick hydrogen bonding whereby A (adenine) bonded to U (uracil) and G (guanine) bonded to C (cytosine) (Béland and Allen, 1994). The “protoribosome” would then have operated as a replicase, via the replication of triplets (the “triplicase” of Poole et al., 1999). The first cycle of replication provided an antisense codon, so that a GCC triplet (the codon for alanine and the most likely first triplet) produced the antisense codon “read” in the opposite direction as GGC (glycine) (Trifonov, 2000). Therefore, as touched on above, if the initial triplet coded for a hydrophilic amino acid (with adenine occupying the central position), then its opposite coded for a

hydrophobic residue (with uracil as the central base) (Béland and Allen, 1994; Konecny et al., 1995).

These triplets, or point (single base) mutations therefrom, tended to code for just those amino acids synthesized by Hennet et al. (1992) in their hydrothermal experiments, i.e., glycine (GGC), alanine (GCC), aspartate (GAC), and serine (UCC). More astonishing is the fact that these amino acids constitute the common sequence in the ancient ferredoxins (Eck and Dayhoff, 1966; Trifonov et al., 2001). This system of direct coding was relatively robust in that mutations not involving the central RNA monomer attracted amino acids with similar side chains and thereby similar properties.

However, during the organic takeover the protoribosome required another surface in place of a mineral such as a peptide sequence rich in positively charged side chains. Such a peptide would have attracted the phosphates of RNA that they might polymerize and still offer the triplet clefts. With amino groups on their side chains, lysine, arginine, and ornithine are equally useful in such a peptide. Mellersh and Wilkinson (2000) demonstrated that poly-adenosine, which includes the clefts AAA expected to have affinity for lysine, does stereoselectively bind L-lysine from dilute aqueous solution of L-amino acids. Moreover, about half the amount of L-arginine and L-ornithine also was found to bind with poly-adenosine. As adenosine was likely the most common of the nucleic acids, and lysine and probably ornithine can be made abiotically, then we have the makings of a feedback cycle that involves the transfer of information.

In this scenario the chance stereochemistry of the short RNA polymer determines the decision of whether it catalyzed the polymerization of D- or L-amino acids into peptides (Mellersh, 1993). To achieve a low energy state, as with mineral growth we might expect RNA to tend to lengthen while preserving either left or right chiralities, i.e., a favorable packing arrangement (Joyce et al., 1984). Were a monomer with the opposite stereochemistry to be added to a growing chain, growth would be thwarted (Sanders, 2003). That filter would have been sufficient to tip the holochirality scale since, despite the presence of a racemic mixture of amino acids in the microcavities only amino acids of the same α -carbon configuration (similar stereochemistry) would preferentially have ended up in peptides, to yield a population of distinctly handed peptides. The rest are eluted to the Hadean Ocean. Some of the retained peptides are eventually fed back in a hypercyclic manner to favor the syntheses of their “stereochemically appropriate” polymerizing template.

Eventually the more robust but less reactive DNA (deoxyribonucleic acid) molecules took over from RNA and thence survived. Braun and Libchaber (2004) demonstrate that secondary convection and thermophoresis, driven by temperature gradients within microcavities in a hydrothermal mound, could concentrate, elongate, and drive the replication of DNA. It remains to be seen if RNA can be elongated and replicated by the same process.

Of course, all this begs the question as to how RNA itself was first generated.

Replication by a natural PCR (polymerase chain reaction) in the mound

According to Koonin and Martin (2005) replication of genetic information and protein coding was probably expedited by populations of virus-like RNA molecules operating within the system of contiguous iron sulfide compartments. Braun and Libchaber (2004) demonstrated in vitro how laminar thermal convection can drive DNA replication and how thermophoresis (thermal diffusion) accumulates the charged polymers (Baaske et al., 2007; Koonin, 2007). These authors point out that such systematic evolution of ligands by exponential amplification is likely to have progressed naturally in porous hydrothermal mounds where the temperature gradient was high and ranged between 50°C and 100°C. This is just the kind of gradient to be expected in off-ridge hydrothermal springs and seepages like Lost City, an alkaline spring that has been operating at least for the last 35,000 years (Früh-Green et al., 2003). While convective temperature cycling encourages the polymerase chain reaction, thermophoresis concentrates DNA and other polymers in cool stagnant zones of the reaction chamber or pore space which act as a thermogravitational microcolumn (Baaske et al., 2007). These first “genes” would stabilize selection. Such “crowding” of newly generated macromolecules would further enhance the assembly of oligomeric structures and their subsequent folding into functional proteins and speed up the rates of reaction along metabolic pathways (Ellis, 2001; Spitzer and Poole, 2009).

Early evolution and the common ancestral community

So far we have seen how geochemical processes may have evolved into biochemical processes. We now enter an evolutionary realm with an empirical base. The universal ancestor of life probably comprised a community of single-celled organisms still housed within its hydrothermal hatchery that possessed all of the attributes common to all bacteria and archaea: the genetic code, the ribosome; DNA; a supporting core and intermediate metabolism needed to supply the constituents of its reproduction; replication; compartmentation from the environment; redox chemistry; and the use of a proton gradient. This last common community (the LCC of Woese, 1998; Macalady and Banfield, 2003) existed in the hydrothermal mound at the dawn of the biochemical revolution where metal sulfide catalysts had been replaced by metalloenzymes, where genes and proteins were complexifying and diversifying into a myriad of functions, and where new pathways and cofactors were being invented to augment and substitute their mineral and RNA precursors (Eck and Dayhoff, 1966; Hall et al., 1971; Martin and Russell, 2003) (Figure 7).

Origin of Life, Figure 7 Evolutionary tree (after Woese et al., 1990; Stetter, 1996; Martin and Russell, 2003). The last common community (the LCC) occupied the mound within which life emerged. It is argued that the first acetogens are the root organisms of the *Bacterial domain* and that the first methanogens evolved into the *Archaeal domain* (the methanogens are found only amongst the archaea). Escape from the vent of these first microbes down into the contiguous ocean floor was only possible when genetically encoded lipid synthesis and cell wall synthesis had been achieved, and when autogenous formyl pterin synthesis as well as *ab initio* ion-pumping mechanisms had been developed for bioenergetic reasons relating to energy conservation efficiency, but in independent lineages of energetically sustainable and genetically replicating ensembles within the network of FeS-bearing compartments (Koonin and Martin, 2005; Russell and Hall, 2006; Martin and Russell, 2007). Here anaerobic microbial communities could be both autotrophic and heterotrophic, the autotrophs utilizing H_2 and formate as substrate while the first heterotrophs could use nitric oxide, elemental sulfur and ferric iron (Fe^{III}) as electron acceptors (Vargas et al., 1998; Philippot et al., 2007; Ducluzeau et al., 2009; see Chapters *Geobacter* and *Shewanella*).

Evolution in the mound extended beyond mere optimization of the acetate and methane reactions (Martin and Russell, 2003). A next step was adaptation that exploited the reduced carbon and energy to be found in waste products and dead cells:

Ferric iron (Fe^{3+}), as an electron acceptor, provided a means of such respiration (oxidative metabolism) (Liu et al., 1997; Vargas et al., 1998), as did elemental sulfur (Philippot et al., 2007) and nitric oxide and its close derivatives (Ducluzeau et al., 2009).

The last common ancestral community occupied the very hatchery in which life first emerged. The acetogenic proto-bacteria and the methanogenic proto-archaea emerged at moderate temperatures (40–50°C) (Brochier and Philippot, 2002) (Figures 1 and 7). A period of high

ambient temperature, caused either by a meteorite impact or a carbon dioxide greenhouse (Kasting and Ackerman, 1986; Kasting and Brown, 1998; Nisbet and Sleep, 2001) could explain why the last common community, residing in the ocean crust contiguous with the mound where life originated, may have been thermophilic, perhaps living at 50–60°C (Gaucher et al., 2003; Schwartzman and Lineweaver, 2004; see Chapter *Basalt (Glass, Endoliths)*).

Conclusions

The onset of life is assumed here to be an inevitable evolutionary outcome of the far-from-equilibrium conditions obtaining on a planet such as ours. These geophysical and geochemical states of the Earth 4 billion years ago are well-established. Life emerged as the ever-renewing catalyst that resolved the potential between carbon dioxide in the atmosphere/ocean and hydrogen in hydrothermal solution. Its hatchery may have been in iron-sulfide-bearing pores within a submarine mound precipitated above a hydrogen-rich alkaline spring. A natural protonmotive force, a consequence of a proton gradient across the inorganic walls of the pores spaces from the acid exterior to the alkaline interior, provided much of the energy for biosynthesis. The autotrophic acetyl coenzyme-A pathway was the first metabolic process to develop within this natural hydrothermal reactor. One variant of the autotrophic pathway produced acetate as waste, the other produced methane. This differentiation between the first microbial processors may have had a profound evolutionary consequence. The protoacetogens perhaps were the forerunners of the bacterial domain, while the protomethanogens evolved into the archaeal domain.

ORIGINS OF THE METAZOA

Daniel J. Jackson
 University of Göttingen, Göttingen, Germany

Synonyms

Animals

Definition

Metazoans – heterotrophic, multicellular organisms that possess eukaryotic cells.

Heterotrophs – organisms that must ingest organic carbon to support growth, unlike plants that are autotrophic and can use light to photosynthesize organic compounds.

Evolutionary concepts

A major event in the time line of Earth's history was the evolution of multicellular animal life, known scientifically as the Metazoa (Knoll and Carroll, 1999; Knoll et al., 2006; Budd, 2008; Love et al., 2009; Xiao and Laflamme, 2009). Metazoans possess eukaryotic cells which contain a distinct membrane bound nucleus, nuclear material (DNA) packaged into multiple linear chromosomes, membrane bound organelles, and modes of cellular division distinct from that of Bacteria and Archaea (Cooper and Hausman, 2009). Metazoans are primarily set apart from plants (also multicellular eukaryotes) in being heterotrophic, and in lacking a rigid cell wall (Campbell et al., 2008).

While all other forms of life (Bacteria, Archaea, and plants) display extensive genetic and metabolic diversity (Venter et al., 2004), the metazoans through 600+ million years of evolution (Peterson et al., 2008) display the greatest variety of locomotory habits, behaviors, and morphologies. Indeed, a fundamental feature of the Metazoa is the morphological diversity displayed by the 35+ (Collins and Valentine, 2001) major groups of animals that constitute the Kingdom Animalia (Carroll, 2001).

Metazoan morphological diversity is essentially generated by two means. Firstly through an ability of

a collection of cells to accurately communicate with one another during the process of development, and secondly for members of that collection of cells to adopt fates with distinct functions. This is most clearly conceptualized when considering the process of metazoan development. Typically, unicellular gametes (sperm and egg cells) fuse to form a zygote (a fertilized egg), which then divides to produce a multicelled embryo and eventually a reproductively mature adult (Gilbert, 2006). During this process, undifferentiated embryonic cells become progressively specified to a particular cell fate (e.g., muscle, neuron, skin, gonad, and eye). Without cell fate specification, tissues (e.g., muscle), organs (e.g., hearts), and organ systems (e.g., digestive system) and the variety of functions that these collections of cells fulfill would not develop (Arendt, 2008).

Evolutionary changes to the metazoan developmental program are ultimately responsible for generating diversity in the adult phenotype. This realization has fuelled the growth of the field of evolutionary-developmental biology (Carroll, 2005). Comparisons of the genes that regulate different metazoan developmental programs now holds the exciting promise of explaining on a molecular level how metazoan morphological diversity is generated (Martindale et al., 2003; Matus et al., 2006). Additionally, recent developments in high-throughput DNA sequencing technologies have seen the completion of a variety of metazoan genomes (King et al., 2008; Putnam et al., 2008; Chapman et al., 2010). These large-scale datasets allow exhaustive comparisons to be made between disparate animal phyla, and deepen our understanding of the genetic innovations that accompanied the diversification of metazoan life.

Related to these efforts are attempts to understand how metazoan life first arose. This requires that we accurately understand how metazoan and pre-metazoan groups are evolutionarily related, and calls on the field of

Origins of the Metazoa, Figure 1 A phylogenetic tree represents a hypothesis regarding the evolutionary relationships of a given set of organisms. Speciation events (indicated by an arrow) generate new lineages of organisms that in turn speciate to generate new "sublineages" thereby increasing diversity. This simplified phylogenetic tree summarizes a recently proposed hypothesis (Pick et al., 2010) that suggests the last common ancestor of the Metazoa (indicated by the red circle) was a sponge-like animal that was descended from a choanoflagellate-like organism.

PARASITISM

Parasitism is a form of symbiosis, in which one organism benefits but the other is harmed. See entry “*Symbiosis*” for further reading.

PEDOGENIC CARBONATES

Eric P. Verrecchia
Université de Lausanne, Lausanne, Switzerland

Synonyms

Secondary terrestrial carbonates; Soil carbonates; Vadose zone carbonates

Definition

Definition and mineralogy

Pedogenic carbonates are authigenic (or secondary) carbonate deposits precipitated in soils (Lal et al., 2000). When found in the soil but directly inherited from parent materials, carbonates are defined as detrital or lithogenic (Kraimer et al., 2005). Pedogenic carbonates are characterized by a wide diversity of shapes, from secondary diffuse micritic (micron-size) crystals inside the soil matrix to coalescent hardened layers, sometimes capping whole landscapes. They are mainly composed of calcium carbonate as calcite and rarely as aragonite (Schaetzl and Anderson, 2005), of magnesian calcite, dolomite (Whipkey et al., 2002), and occasionally of iron-rich carbonate such as ferroan calcite, siderite, and ankerite (Table 1). Iron-rich carbonates are generally found in organic-rich soils and soils under the influence of

water-table fluctuations with active oxidation–reduction processes.

Origin

Carbonate physicochemical equilibria

Various processes are involved in pedogenic carbonate formation. The first significant process is related to the leaching of carbonate through the soil profile. In the upper horizons, inherited calcium carbonate is dissolved by carbon dioxide enriched waters and displaced in solution toward deeper horizons where it precipitates. This precipitation is supposed to occur if the concentration in Ca^{2+} increases, the pCO_2 decreases, or if soil solutions concentrate due to water loss (evaporation). In other words, all these processes are driven by the following general equations when lithogenic (detrital) carbonates are involved:

A second process is related to the transformation, in surficial environments, of primary minerals which can also lead to the precipitation of pedogenic carbonates. For

Pedogenic Carbonates, Table 1 Mineralogy and occurrence of pedogenic carbonates

Mineral	Formula	Occurrence of pedogenic carbonate
Calcite	CaCO ₃	All latitudes
Aragonite	CaCO ₃	Detected in some temperate carbonate soils
Magnesian calcite	[Ca _{0.90–0.95} , Mg _{0.05–0.10}]CO ₃	Detected in carbonate soils from evaporitic and tropical environments
Dolomite	(Ca, Mg)(CO ₃) ₂	Detected in carbonate soils from evaporitic or paralic environments
Ferroan calcite	[Ca(Fe ^{II})]CO ₃	In carbonate soils with an active iron cycle
Siderite	[Fe ^{II} (Ca, Mg)]CO ₃	In carbonate soils with active oxidation–reduction processes and organic matter
Ankerite	[Ca, Fe ^{II} (Mg, Mn)](CO ₃) ₂	In carbonate soils with active oxidation–reduction processes and organic matter

example, weathering of alkaline feldspar (plagioclase) by water enriched in carbon dioxide leads to the solubilization of calcium ions as well as hydrogen carbonate (i.e., bicarbonate) ions according to the equation:

The presence of calcium and hydrogen carbonate ions can lead to pedogenic carbonates, according to [equation \(4\)](#) if, for example, appropriate pH conditions are reached. Such pedogenic carbonates include carbonate cements, calcitic coatings associated with pores (mostly related to soil desiccation and/or root suction), and matrix impregnation by carbonate crystals of various sizes, from sparite (>20 µm) to micrite (<2 µm), during displacement of equilibria in soil solution (Deutz et al., 2001).

Although often presented as the engine of main pedogenic carbonate accumulations, these physicochemical equilibria remain fairly theoretical and do not incorporate all the complexities in the field. Processes in nature cannot be reduced to a simple set of equilibrium equations. First, kinetics of the carbonate system depend on many factors such as CO₂ diffusion as well as relationships between soil pores and water or the presence of specific ions such as Mg²⁺ or phosphorous, making the system much more complex than it seems. Second, the role of life is barely taken into account in such equations. Indeed, pedogenic carbonates are probably much more related to biomineralization processes (directly or indirectly) rather than simple displacement of physicochemical equilibria. To illustrate this point, just consider the distribution of the pCO₂ in a soil. The deeper the horizon, the higher the pCO₂. So why are pedogenic carbonates precipitating in the solum where the conditions seem to be the least favorable, that is, in the deeper horizons? The explanation can be found when the contribution of life is explored.

The role of microorganisms

Bacteria undoubtedly play an important role in the formation of pedogenic carbonates. It has been demonstrated that precipitation of CaCO₃ could be the reaction of heterotrophic bacterial guilds to an increase in soil

organic matter. Another example is given by the oxalate–carbonate pathway (Cailleau et al., 2005). In soils enriched in oxalate by plants and/or fungi, oxalotrophic bacteria can use oxalic acid and/or calcium oxalate as an electron donor and a carbon source. The result is a change in soil pH as well as the production of hydrogen carbonate ions. Calcium carbonate can precipitate when pH is high enough and the carbonate species and calcium are in appropriate concentrations, even in acidic environments such as tropical soils. Therefore, bacterial activity not only contributes to pedogenic carbonates but also changes chemical soil properties. In soils where nitrate and sulfate minerals are available, heterotrophic reducing bacteria can use these substrates as electron donors to produce CaCO₃ (as long as calcium is present). When iron is present with calcium sulfate, bacterial activity can lead to the concomitant precipitation of calcium carbonate and iron sulfide. This process assumes some soil redox conditions. Another example is given by methanogenic bacteria which can transform soluble organic matter from the soil solution percolating in deep horizons. This transformation occurs in the phreatic zone, under soils enriched in organic matter or peats, that is, in a distinctly anoxic environment. Secondary calcium carbonate appears as coatings in cracks of the parent rock. In conclusion, bacteria influence the kinetics and the reactions involved in pedogenic carbonates, even if their direct role in crystal nucleation is still difficult to prove beyond doubt. In any case, bacteria influence the composition of the soil solution and the biogeochemical cycles of major elements.

Fungi are also important factors in the formation of pedogenic carbonates. Their growth is related to the development of mycelia which can form a network in the soil. In their need to absorb Ca²⁺ for their metabolism, filamentous fungi developed the ability to concentrate these ions in their thallus as calcium oxalate or calcium carbonate salts, inside or outside their membrane. In addition, fungi excrete large quantities of organic acids, especially oxalic acid. Two common fungal features in pedogenic carbonates can be observed: calcified filaments and hyphae associated with needle fiber calcite (called NFC; [Figure 1a](#) and [b](#)). Calcified filaments are fungi covered with oxalate crystals ([Figure 1c](#) and [d](#)). The way in which fungi can form such accumulations of calcium oxalate around their cell walls is still unclear, although the excretion of oxalic acid must play a role in the formation of calcium oxalate

as well as in the dissolution of carbonate parent rocks. It is likely that part of the dissolution products diffuse inside the pores of the matrix and reprecipitate as secondary calcium carbonate a bit further away, contributing to soil matrix induration. Regarding the oxalates, they constitute a carbon and an electron source for oxalotrophic bacteria. As stipulated above, this oxalotrophic pathway also contributes to secondary calcium carbonate accumulations in soils. The origin of needle fiber calcite is also controversial (Verrecchia and Verrecchia, 1994; Cailleau et al., 2009b), often interpreted as a purely physicochemical product related to plant suction or other specific soil conditions. In fact, NFC seems to be mainly related to fungal activity, as it is always associated with fungal filaments (rhizomorphs). NFC crystallographic properties show that the crystals are complex, often polygenic, and undergo early diagenetic evolution, such as epitactic growth, inside the soil pores. Finally, some authors have observed nanorods associated with fungal filaments. These features are often considered either calcitic nanocrystals, a former stage of NFC, or mineralized bacteria. Recent research seems to demonstrate that these nanorods are decayed cell wall fibrous material from fungal rhizomorphs (Bindschedler et al., 2010). This material acts as a template for calcium carbonate

precipitation, leading to a mineralized mesh covering soil aggregates (Cailleau et al., 2009a). In conclusion, microorganisms play a prominent role in pedogenic carbonates by changing the biogeochemical conditions in microenvironments, by their direct influence on the precipitation of calcium carbonate, as well as their potential role to serve as a template for CaCO_3 crystal nucleation.

The role of the rhizosphere

The impact of the rhizosphere in the formation of pedogenic carbonates is related to two main processes: dissolution of carbonate parent material, leading to the redistribution of calcium carbonate in the soil matrix, and indirect and direct precipitation of carbonate due to root activity (Becze-Deak et al., 1997). The dissolution of carbonate parent rock by roots increases the soil porosity as well as the saturation index of the soil solution in carbonates. Although dissolution seems to be a destructive process, it is associated with a redistribution of soil carbonates leading to soil induration. Indeed, when organic acids are excreted by roots, dissolution of lithogenic carbonate occurs, increasing the concentration of dissolved carbonate inside the soil solution. On the other hand, when conditions are dry, roots need water: they pump

water from the soil solution, consequently increasing the concentration of calcium and carbonate ions in the solution around the root, leading to periporal precipitation of secondary calcium carbonate. Simple soil desiccation through the root channel may produce the same results. Such a cementation process, i.e., impregnation by secondary calcium carbonate of the soil matrix around root traces, is at the origin of rhizoliths (pedogenic carbonates having the shape of roots, Figure 2a and b). Not only do roots excrete large quantities of organic acids, protons, and even hydrogen carbonates, but they also absorb potassium, nitrogen, water, and calcium. Some plants have the ability to accumulate CaCO_3 in their vacuole in order to detoxify a possible excess of Ca^{2+} . These cellular biomineralizations are called calcified root cells (Jaillard et al., 1991; Figure 2c) and they are pedogenic carbonates directly related to the interaction of plant roots with soil solution. Finally, regarding pedogenic carbonate nodules found in present-day soils as well as paleosols, they probably result from the complex interactions between microorganisms, plant roots, and the composition of soil phases (soil solution and gas).

Animals may also play an important role in pedogenic carbonate formation inside the rhizosphere. For example, termites both mine carbonate from deep parent rock (bioturbation) and biomineralize the calcite in their body (Liu et al., 2007). Earthworms contribute to calcium carbonate accumulation in soils (Canti and Pearce, 2003). They excrete calcitic biospheroids in their casts (Figure 2d). The biospheroid formation occurs in the

calciferous cells of the epithelium that secrete amorphous calcium carbonate, crystallizing in the lumen of the esophageal pouch. These spheruliths of calcite are usually up to 2 mm in diameter with an average weight of 1.5 mg. They indicate the presence of earthworms. When, through diagenesis, obvious traces of earthworms are missing in buried paleosols, the presence of biospheroids provides good arguments for relative stability of the soil-sedimentary environment, i.e., no rapid burial and no drastic prolonged water stress.

Calcretes

The term “calcrete” should only be used for complex terrestrial carbonate accumulations, often hardened and showing specific features such as nodular, lamellar, massive, and laminar horizons. However, calcretes are characterized microscopically by many features similar and/or related to pedogenic carbonates (root traces, calcified root cells, needle fiber calcite, matrix nodulization, calcitic coatings), which explains why the term has been inappropriately used as an equivalent of pedogenic carbonates in many studies (Nash and McLaren, 2007). The origin of vadose calcretes is still controversial. Soil scientists consider calcretes as soils: calcium carbonate is leached from the upper horizon toward the lower horizon, until CaCO_3 infills all the pores leading to a plugged horizon. Sedimentologists interpret calcrete as complex (polygenic) sedimentary formations where pedogenesis, biogenic processes, and sedimentation episodes interact. In this case,

Pedogenic Carbonates, Figure 2 Pedogenic carbonates and the rhizosphere: (a) vertical root traces inside a paleosol developed on eolianites, Israeli Mediterranean coast. Scale in centimeters. (b) cross section of a root. From *center* to *periphery*: hole left by the decayed root, accumulation of dense pedogenic micrite, transition to secondary accumulation of pedogenic micrite diffusing toward the sandy matrix, carbonate-depleted zone, and sandy host rock. Plane-polarized light. Bar: 25 mm. (c) longitudinal section of a calcified root. The cells form a hollow tube. Loessic soil, Bk2b horizon, Wallertheim, Germany. Cross-polarized light. Bar: 500 μm . (d) calcitic biospheroid formed by earthworms. Carbonate alluvial soil, Rhone River terrasse, Holocene, France. Plane polarized light. Bar: 200 μm .

calcretes record a long history of landscape evolution whereas, in the soil model, calcretes are only related to a single process of dissolution and reprecipitation in a relatively stable environment. For example, for soil scientists, mature calcretes are characterized by a laminar horizon resulting from cementation inside a carbonate-rich perched water table, in which the soil solution is unable to percolate further down because it is stopped by the plugged horizon. This horizon is therefore posterior to the upper soft soil. Sedimentologists consider this laminar horizon as a surficial deposit (in contact with the atmosphere) related to cyanobacterial activity and sedimentary processes (weak runoff, eolian dust incorporation). The upper soft soil, where present, is therefore posterior to the laminar crust.

Pedogenic carbonates as a carbon sink?

The question of a potential role of pedogenic carbonates as a carbon sink is often asked (Lal et al., 2000; Landi et al., 2003; Cailleau et al., 2004). Researchers consider that the residence time of carbon in pedogenic carbonates is 3–4 orders of magnitude higher than that of soil organic matter. In order to answer this question, the origin of calcium (Ca) has to be considered (Van der Hoven and Quade, 2002). There are two possible origins for the Ca in pedogenic carbonates. Ca can be inherited from weathering of preexisting CaCO_3 (e.g., dust or parent rock limestone). Recrystallization of pedogenic CaCO_3 allows atmospheric CO_2 catchment but, in contrast, fossil CO_2 has been released during weathering, leading to a zero net balance for the carbon cycle. Thus, this process has to be considered only a molecular CO_2 substitution from fossil limestone to pedogenic carbonates. A second possible origin of Ca is when released from the weathering of noncarbonate minerals (see e.g., Equation 5) and precipitated as CaCO_3 . In this case, the catchment of atmospheric CO_2 by the released Ca into authigenic pedogenic carbonates acts as a carbon sink.

Summary

Pedogenic carbonates are authigenic deposits found in soils. Their origin is related to biological activity involving bacteria, fungi, roots, and soil animals, as well as complex kinetics between minerals and soil solution. Consequently, their biogeochemical signature as a proxy should be used with caution to reconstruct paleoenvironments (Quast et al., 2006). On the other hand, they can constitute a carbon sink if the cations originate from noncarbonate substratum.

Microbiology of perennially frozen ground

Definition

Permafrost is the ground (soil or rock) beneath the surface of the earth that remains at or below 0°C for at least two consecutive years. Permafrost is defined on the basis of temperature. It is not necessarily frozen; moisture in the ice form may or may not be present (van Everdingen, 1998). For microbiology is important the usage of permafrost that requires also the presence the moisture in the ice form. In other cases the following terms are used: (a) overcooled, because the freezing point of the included water may be depressed several degrees below 0°C; (b) frosty, if the moisture content is close to zero (Basic foundation of geocryology, 1959).

Introduction: Why permafrost?

Because the occurrence of a viable Cenozoic generation of microorganisms within the permafrost is intriguing as a window into microbial life as it was before the impact of humans (Tiedje et al., 1994) and as a storage of the ancient genetic pool – the preexisting life, which hypothetically has long since vanished on the Earth surface.

Because the answer for fundamental question “how long the life might be preserved,” could be found within permafrost – natural observatory of viable systems over geological time, where paleoorganisms realize unknown possibilities and unique mechanisms of physiological and biochemical adaptation that allow them to maintain viability for very long cold periods.

Because permafrost represents a wide range of possible habitats and inhabitants on the planets without obvious surface ice such as in Mars, and if life existed during the early stages of development on this Earth-like planet, then, similar to the Earth, remnants of primitive forms may be found within frozen material.

Because permafrost thawing due to anthropogenic or natural processes exposes ancient life to modern ecosystems and ancient biota became easily involved anew in present-day ecological processes.

Only these problems demonstrate the significance and perspectives of permafrost microbiology.

Cryobiosphere

The terrestrial Cryosphere consists of two parts: Glaciosphere (snow and ice) and Cryolithosphere, the frozen part of the Lithosphere, containing long-term and seasonally cryogenic formations with ancient and recent viable microorganisms, respectively. The comparison of

number of the cells survived over geological time at temperature above 0°C in halite (Lipman, 1928; Dombrowski, 1963; Norton et al., 1993; Denner et al., 1994; Vreeland et al., 2000; Stan-Lotter et al., 2003) and amber (Galippe, 1920; Cano and Borucki, 1995; Lambert et al., 1998; Greenblatt et al., 1999) and at temperature below 0°C in Cryosphere, shows that the latter is the most spread and rich terrestrial depository of ancient viable microorganisms. Cryosphere that is found between the upper atmospheric layers (Wainwright et al., 2003), including overcooled cloud droplets (Sattler et al., 2001) and the bottom of Antarctic Ice Sheet, represents a significant part of Biosphere, the Cryobiosphere, where life is confined in ice and permafrost.

Icy world

Biota of Greenland Ice Sheet, 120,000-years old, and Antarctic Ice Sheet, ~400 Kyr have been widely studied to the depth more than 3 km (Abyzov, 1993; Kapitsa et al., 1996; Priscu et al., 1998; Karl et al., 1999; Petit et al., 1999; Skidmore et al., 2000; Deming, 2002; Miteva et al., 2004; Miteva and Brenchley, 2005). The age of the oldest glacial ice as well as immured bacteria are still under discussion: >500,000 years at Guliya ice cap on Tibetan Plateau (Thompson et al., 1997; Christner et al., 2003), ~2 million years at the bottom of Vostok ice core (Salamatin et al., 2004) or even ~8.1 million years (Sudgen et al., 1996; Bidle et al., 2007) in Beacon Valley, Antarctica. Microbial population and traces of life in ice sheets are interpreted to be the Earth's most representative models of extraterrestrial icy habitats (like Jupiter's Ice-covered moon Europa, or Enceladus – Icy moon in Saturn system).

The initial number of mostly air-borne microorganisms isolated from snow and seasonally ice covers is not great (10^2 cells per ml) and of the same order as viable cells within the ancient ice sheets core's. Such fact could be interpreted as absence of reduction of microbial population once immured in ice for thousand years and could be explained, for example, by the near zero background radiation in the ice. The ultra small ($<\mu^3$) cells dominated in its population (Miteva and Brenchley, 2005) and the number of viable cells in ice cores increases sharply in the presence of dust particles (Abyzov, 1993). Unlikely they occupying the narrow liquid veins (Price et al., 2004) only, because data from Vostok cores showed that the most abundant are the upper layers in spite of extremely low temperatures (-50°C). Distribution of cells along the hole indicates that the populous of viable cells in Antarctic Ice Sheet decrease with the increasing age of embedding ice.

Greenland ice cores also indicate a good preservation of relatively young, 2–4 Kyr, genomic DNA (Willerslev et al., 1999), as well as bacterial and plant viruses varied in age 0.5–100,000 years (Castello et al., 2005). Therefore, freezing prompts viral endurance. Unfortunately, this relates to human viruses too – in Arctic, RNA of influenza

A is preserved in high concentrations in lake's seasonally ice (Shoham, 2005; Zhang et al., 2006).

The last review of icy Biosphere made by Priscu and Christner (2004) and the recent level of the problem are shown in the book *Life in Ancient Ice* Castello and Rogers (2005).

Cryolithosphere

However, the most inhabited part of Cryosphere, represented by Cryolithosphere or permafrost, underlie about a quarter of the Earth's land surface. Permafrost is the integral part of Arctic (the northern reaches of North America and Eurasia) and ice-free regions of Antarctica and Greenland. The so-called, Alpine permafrost is wide spread in the high mountains of all continents: Europe, western China, and both Americas, as well as offshore permafrost occupied the polar shelf surrounding Arctic and, probably, Antarctica.

This considerable frozen mass, up to several hundreds of meters deep, where microorganisms are adsorbed on organic or mineral particles, harbors a numerous (up to dozen millions cells per 1 g of dry soil – gdw) of various ecological and morphological viable microbial groups survived under permafrost conditions since the time of its formation. They have been isolated from frozen cores with permanently constant ground temperatures (–1)–(–2)°C near the south border of permafrost in Siberia and down to lowest in Arctic: –17°C, on 80°N, Ellesmere Island – the most northern latitude (Steven et al., 2007) and in Antarctica: –27°C on 78°S, Dry Valleys – the most southern latitude (Gilichinsky et al., 2007a). Viable microorganisms were found down to 400-m depth in Mackenzie Delta (Gilichinsky, 2002) and up to 4700-m elevation in Qinghai-Tibet Plateau (Zhang et al., 2007). The age of the isolates corresponds to the longevity of the permanently frozen state of the sediments and dates back from few thousand to 2–3 million years in northeastern Siberia and to 5–8 million years and probably older in Antarctica (Gilichinsky et al., 2007a). This great mass of living matter is peculiar to permafrost only, and taken into account the thickness of Cryolithosphere (50–1000 m), it is easy to conclude that permafrost contain a total biomass of cold adapted microorganisms many times higher than that of the modern soil cover.

In contrast to the ice sheets, where the overwhelming majority of discovered microorganisms came from the atmosphere, microorganisms isolated from permafrost are similar to those of surface and aquatic cold ecosystems and habitats. The total cell number counted by epifluorescence microscopy reached 10^7 – 10^8 cells/gdw in Arctic (Siberian and Canadian) permafrost (Vorobyova et al., 1997; Steven et al., 2007) and 10^5 – 10^6 cells/gdw in Antarctic permafrost (Gilichinsky et al., 2007a). This indicates the initial low level of microbial population in Antarctic Dry Valley environment in comparison with Arctic. Antarctic permafrost also is several orders of magnitude lower in the number of viable cells, and has less

microbial diversity, than Arctic one. The fraction of the total bacterial population that could be recovered from frozen samples (the number of cells that grow on nutrient media) varied 10^3 – 10^7 cells/gdw, ranging 0.01–1.5% of the total amount counted by epifluorescence microscopy (Vishnivetskaya et al., 2000) and this conclusion is supported by experimental data from different cores and regions. Note that cold adapted organisms of the microbial community within the permafrost has the optimal growth at room temperature, i.e., according to the growth temperature classification of Morita (1975, 1997), are not psychrophilic, or restricted to permanently cold habitats (Gounot, 1986), but are predominantly psychrotrophic.

Permafrost is not only bacterial (aerobic and anaerobic, spore-forming and spore less, Gram-positive and Gram-negative) archival depository, but also contain viable cyanobacteria and green alga (Vishnivetskaya, 2009), yeast (Dmitriev et al., 1997; Faizutdinova et al., 2005), actino- and micromycetes (Kochkina et al., 2001), as well as their metabolic-end products: biologically active macromolecules – free intra- and extracellular enzymes (invertase, catalase, protease and amylase) (Vorobyova et al., 1996), pigments (chlorophyll *a*, *b*, and pheophytin) (Erokhina et al., 2004), and biogenic gases, such as methane (Rivkina et al., 2007) and even biological objects of higher level: mosses (Gilichinsky et al., 2001), seeds (Porsild et al., 1967; Yashina et al., 2002), and protozoa (amoeba, infusorium and flagellates) (Shatilovich et al., 2005).

This is why permafrost could be considered as a unique subsurface complex, where the long-term impact of constant physicochemical regimes, including subzero temperatures, should be regarded not as the extreme and limiting but rather as a stabilizing factor. The frozen environment is characterized by solid and liquid water phases. The solid phase (ice) makes up 93–98% of total water volume and serves as a cryoconservant, a reagent favored for conservation of biological objects at temperatures below 0°C. At subzero temperatures the rates of biochemical reactions and biological processes become extremely low, and ensure preservation of biological system. Concomitant with the solid phase, the remaining few percent of the water is in an unfrozen state and occurs most commonly as thin films enveloping soil particles and, occasionally, as brine pockets. In contrast to ice, the unfrozen water serves as a cryoprotector and plays the leading role in the preservation of microorganisms. These films, by coating the organic and mineral particles, protect the viable cells sorbed onto their surface from mechanical destruction by growing ice crystals and make possible the mass transfer of microbial metabolic end-products within the permafrost, preventing the cell's biochemical death. This is why the unfrozen water serves as a main ecological niche for microorganisms (Gilichinsky et al., 1995).

The quantity of the unfrozen water and the thickness of its films are independent of the total ice content, but decrease with subzero temperature decreasing (Nersesova and Tsytoich, 1966; Anderson, 1967). Given these

characteristics of Arctic permafrost at temperatures between -3 to -12°C , the amount of unfrozen water can be estimated as 3–8% by weight, which depends upon the ion content and texture. In the coarse Antarctic sands, because of the low temperatures, the unfrozen water values are so small that the instrumental methods fail to record them. Unfrozen water in Antarctic permafrost must, therefore, only be firmly bound “liquid” water with binding molecules, which indicates a “biologically dry” permafrost environment.

Life below freezing point

The subzero temperatures themselves are not the limiting factor, and microorganisms are able to grow at these temperatures if the media is not frozen, at least as low as -10°C for one year in the presence of glycerol as cryoprotector (Gilichinsky et al., 1993). This correlates with the lower temperature limit for microorganisms growth (Russell and Hamamoto, 1998), but the conditions of experiments are too far from the permafrost environment in situ. Such conditions (temperatures down to -10°C and up to 200 g/L salt concentrations) are present within the lenses of cryopegs – overcooled water brines in permafrost, where metabolic activity without cell division was shown using resazurin reduction as indicator (Bakermans et al., 2003) and uptake of D- $[^{14}\text{C}]$ glucose into the bacteria biomass (Gilichinsky et al., 2003, 2005). Hypersaline waters are defined as having salt concentrations greater than that of sea water (3.5% w/v) while the salinity of cryopeg lenses reaches 15–20%.

The unfrozen water films, high in salts, represent the same microcryopegs, and most investigators indicate that at least part of permafrost community (20%, according to Steven et al., 2006) growth at temperatures between -2 and -10°C (Shcherbakova et al., 2004, 2005; Ponder et al., 2006; Rodrigues et al., 2006; Bakermans et al., 2006), while 95% of the isolated cells of aerobic bacteria did not grow at temperatures above 30°C (Gilichinsky et al., 1995).

Biotic survival in the late Cenozoic frozen and overcooled high-salt aquatic environments and Permian-Triassic salt deposits (Stan-Lotter et al., 2002, etc.) indicates unknown bacterial adaptations. It remains to be determined whether the salt tolerance of these cells may also be associated with cold tolerance on a geological scale. Experiments showed that under subzero temperatures halophilic bacteria survive better than non-halophilic and remain viable at -80°C in the presence of 25% NaCl and extreme halophiles require NaCl concentrations above 15.6% (w/v) for growth (Rothschild and Mancinelli, 2001; Mancinelli et al., 2004).

The permafrost, mostly psychro-halo-tolerant microbial community, has been described as “a community of survivors” (Friedmann, 1994), with the starvation-survival lifestyle as the normal physiological state (Morita, 2000). We can conclude that this community represents the only the selected members of buried surface or

aquatic ecosystems adapted to permafrost conditions and have efficient repair mechanisms that allow for these and not, for example, other tundra organisms to continue to live in permafrost (Ponder et al., 2006). This is why from one hand, permafrost bacteria have been previously isolated from Arctic tundra soils (Bab’eva and Sizova, 1983), and from the another one – many types of bacteria present in the Arctic soils, were not isolated from permafrost samples (Shi et al., 1997).

The preservation of a viable microbial community in permafrost over geological times at subzero temperatures raises the significant possibility of metabolic reactions for these conditions. The following facts provide indirect evidence that ancient microorganisms can be active in the permafrost nutritional-temperature regime and allows speculation concerning the possibility of biogeochemical processes in situ: the ability of immobilized enzymes in permafrost to become instantly activated (Vorobyova et al., 1996); the presence of usually metastable ferrous sulfides (Siegert, 1987) and nitrites (Jansen and Bock, 1994); the ability of cells to grow on media after being exposed to ground radiation during up to millions of years. This ability implies their capacity to repair DNA damage even in the frozen environment, i.e., at the stable rate of damage accumulation a comparable rate of repair must also exist.

However, the question about the metabolic state of microorganisms, microbiological and biogeochemical processes, and life forms within permafrost still remains open to debate. For recent microbial communities measurements show that Antarctic lichens may be active at a temperature of -17°C (Kappen et al., 1996) and evidence was obtained of low rates of bacterial DNA and protein synthesis at subzero temperatures (-12 to -17°C), which indicates that the organisms divided in snow at the South Pole (Carpenter et al., 2000). For ancient microorganisms to the moment we can refer only to results of few experiments, suggesting that permafrost microorganisms are not, as previously thought, in a frozen resting state. The incorporation of ^{14}C -labeled acetate into lipids shows that in permafrost 2–3 million years old, at temperatures down to -20°C , anabolic metabolism is possible, resulting in the formation of bacterial lipids with the minimum 160 days doubling time (Rivkina et al., 2000). Also, using the ^{14}C -labeled substrates (H^{14}CO_3 and $^{14}\text{CH}_3\text{CO}_2$), hydrogenotrophic and acetoclastic methanogenesis was measured in the late Pliocene to Holocene permafrost samples at temperatures down to -16.5°C (minimal permafrost temperature in Arctic) and even to -28°C (permafrost temperature in Antarctica), indicating the energetic metabolism – the ability of microorganisms to carry out redox reactions after thousands to millions years of existence in permafrost (Rivkina et al., 2004, 2005, 2007; Gilichinsky et al., 2007).

From the biological point of view, taking into account the natural radiation background of 1–2 mGy/year, the dose from radio nuclides diffused through the permafrost is far from sufficient for complete sterilization even the

oldest microbial complexes, i.e., it is not fatal to viable cells, but it is highly enough to cause selection effect and to destroy the DNA of ancient cells. The calculated data correlate with the number of viable cells in permafrost of different age and with experimental results. The cell viability and growth on media implies a high capacity for DNA repair and we can conclude that DNA repair occurs in the frozen environment, i.e., at the stable rate of damage accumulation, while a comparable or lower rate of reparation also exists (Gilichinsky et al., 2007b). The same suggestion made Johnson et al. (2007). Using a combination of molecular biology techniques and direct measurement of CO₂ production from permanently frozen samples they find strong evidence that long-term survival is closely tied to cellular metabolic activity and DNA repair as a mechanism in sustaining bacteria viability.

The DNA preservation and reparation in permafrost is a huge area of important problems. Microbial communities began now characterized by newly emerging culture-independent molecular techniques – PCR amplification of diverse environmental 16S rRNA genes as well as the diversity of fungi – by 18S rRNA genes. Long-term persistence of bacterial, archaeal, and fungal DNA were found in relatively young, late Pleistocene-Holocene, Canadian (Steven et al., 2007) and Tibetan (Zhang et al., 2006) permafrost and within late Pliocene–Pleistocene Siberian (Shi et al., 1997; Lydolph et al., 2005; Vishnivetskaya et al., 2006) and Antarctic (Spirina et al., 2003; Gilichinsky et al., 2007a). These studies shows that DNA, usually degraded rapidly in most environments, survived within permafrost over geological time and the question is how long the DNA could be preserved. Series papers (Willerslev et al., 2003, 2004; Hansen et al., 2006; Johnson et al., 2007) on the basis of observed rates of DNA degradation indicate a limit of ca. 400–600,000 years beyond which PCR amplifications are prevented. This conclusion is still under discussion because based on the same few samples only and has not the statistical support and even its authors agree that studied organisms maintain a metabolic activity to repair DNA damages. Also because in another studies the viable microorganisms were isolated and DNA was extracted from permafrost samples up to 3–5-million-years old.

Conclusion

Microbiological and molecular studies of paleobiological objects in permafrost expand our knowledge about spatio-temporal limits of Biosphere and form the basis for new knowledge in various scientific multidisciplinary (geo/bio/cryo) fields: quaternary geology, geocryology, bacterial paleontology, geo- cryo-, paleo-, and exobiology. Also, the advances in biotechnology evidently indicate that in the visible future the genetic recourses will be even more important than geological one, and the permafrost microorganisms, as well as their metabolic-end products might be of potential value for industrial application, for

example, on the base of abilities to operate at subzero temperatures.

 University of Lausanne, Lausanne, Switzerland

Definition

Phosphorus is a chemical element (P) with atomic number 15, which occurs mainly in the form of phosphate (PO_4^{3-}). P is essential for life, but may negatively impact existing ecosystems when present in excess. The P cycle is tightly coupled with the carbon cycle through photosynthetic and biogeochemical weathering processes.

Introduction

Phosphorus (P) occurs most widely in the form of phosphate (PO_4^{3-}) and plays – as an essential and often limiting nutrient – an important role in the overall functioning of the biosphere and its environment. It is in this capacity that this element is heavily recycled within the biosphere, and the most important source is its release from preexisting stocks within the biosphere. Its primordial source, however, is related to the biochemical weathering of P-containing rocks and the consequent transfer into the biosphere (Lerman et al., 1975; Froelich et al., 1982; Compton et al., 2000; Ruttenberg, 2005).

P exerts important interactions with the carbon cycle through the interfaces of photosynthesis and biogeochemical weathering. In the first case, P may drive the transformation of atmospheric CO_2 into organic C in those ecosystems where P is limiting, and in the second case, the amount of atmospheric CO_2 determines the amount of P liberated from its host rock and transferred to the biosphere (Mackenzie et al., 1993).

The study of the present-day P cycle on a worldwide scale together with the reconstruction of temporal changes in the P cycle during the Earth's history is essential in the reconstruction of global environmental change at present and in the past (Cook and McElhinny, 1979; Bendor, 1980; Arthur and Jenkyns, 1981; Filippelli and Delaney, 1994; Föllmi, 1995, 1996; Trappe, 1998; Slomp and Van Cappellen, 2007).

The global phosphorus cycle

The principal release mechanism of P to the environment consists in the biogeochemical weathering of P-containing crystalline, volcanic, and sedimentary rocks (Froelich et al., 1982; Föllmi et al., 2009). Volcanic and hydrothermal activity provides only minor amounts of P, if at all – except eventually for basaltic volcanism and the formation of P-enriched deposits such as carbonatite and anorthosite (Baturin, 1982; Notholt et al., 1989; Feely et al., 1990). Once transferred into the biosphere, P predominantly resides in soils, where it becomes part of the organic fraction and may also be included into secondary mineral phases such as iron oxyhydroxides (Walker and Syers, 1976; Frossard et al., 1989). Approximately 3–6% of the total terrestrial P stock is incorporated in vegetation, with organic P:C ratios of 1:500–1:800 (Delwiche and Likens, 1977; Berner et al., 1993).

P is transported to oceans via rivers and wind, where the eolian fraction corresponds to 7–15% of the total preanthropogenic P freight (Graham and Duce, 1979; Compton et al., 2000). Rivers transport P as dissolved inorganic P (DIP), dissolved organic P (DOP) and in particulate forms (PIP, POP). PIP transport occurs in the form of detrital P and P absorbed onto iron oxyhydroxides and clay minerals (Meybeck, 1982, 1993; Compton et al., 2000; Seitzinger et al., 2005; Harrison et al., 2005). Recent estimates show that presently approximately 85% of the total P freight to the ocean is transported in particulate form (Beusen et al., 2005).

Once in the ocean, P enters a recycling loop between organic and inorganic forms, and only approximately 1% of the total amount of P used in primary productivity is permanently stored in the sedimentary reservoir per time unit. The P:C ratio in oceanic primary producers is significantly lower than that for terrestrial plants and amounts to 1:106–117 (Redfield, 1958; Anderson et al., 2001). The present-day residence time of oceanic P is estimated as between 10,000 and 17,000 years (Ruttenberg, 1993, 2005; Colman and Holland, 2000).

Recent attempts to quantify P reservoirs and flux rates on a global scale have been published in Mackenzie et al. (1993), Compton et al. (2000), Harrison et al. (2005), Beusen et al. (2005), and Ruttenberg (2005).

Phosphorus, microbes and life

The degree to which P may limit primary productivity in certain ecosystems is judged differently in the literature (Falkowski et al., 1992; Tyrrell, 1999). A vast array of

Definition

Phosphorus is a chemical element (P) with atomic number 15, which occurs mainly in the form of phosphate (PO_4^{3-}). P is essential for life, but may negatively impact existing ecosystems when present in excess. The P cycle is tightly coupled with the carbon cycle through photosynthetic and biogeochemical weathering processes.

Introduction

Phosphorus (P) occurs most widely in the form of phosphate (PO_4^{3-}) and plays – as an essential and often limiting nutrient – an important role in the overall functioning of the biosphere and its environment. It is in this capacity that this element is heavily recycled within the biosphere, and the most important source is its release from preexisting stocks within the biosphere. Its primordial source, however, is related to the biochemical weathering of P-containing rocks and the consequent transfer into the biosphere (Lerman et al., 1975; Froelich et al., 1982; Compton et al., 2000; Ruttenger, 2005).

P exerts important interactions with the carbon cycle through the interfaces of photosynthesis and biogeochemical weathering. In the first case, P may drive the transformation of atmospheric CO_2 into organic C in those ecosystems where P is limiting, and in the second case, the amount of atmospheric CO_2 determines the amount of P liberated from its host rock and transferred to the biosphere (Mackenzie et al., 1993).

The study of the present-day P cycle on a worldwide scale together with the reconstruction of temporal changes in the P cycle during the Earth's history is essential in the reconstruction of global environmental change at present and in the past (Cook and McElhinny, 1979; Bendor, 1980; Arthur and Jenkyns, 1981; Filippelli and Delaney, 1994; Föllmi, 1995, 1996; Trappe, 1998; Slomp and Van Cappellen, 2007).

The global phosphorus cycle

The principal release mechanism of P to the environment consists in the biogeochemical weathering of P-containing crystalline, volcanic, and sedimentary rocks (Froelich et al., 1982; Föllmi et al., 2009). Volcanic and hydrothermal activity provides only minor amounts of P, if at all – except eventually for basaltic volcanism and the formation of P-enriched deposits such as carbonatite and anorthosite (Baturin, 1982; Notholt et al., 1989; Feely et al., 1990). Once transferred into the biosphere, P predominantly resides in soils, where it becomes part of the organic fraction and may also be included into secondary mineral phases such as iron oxyhydroxides (Walker and Syers, 1976; Frossard et al., 1989). Approximately 3–6% of the total terrestrial P stock is incorporated in vegetation, with organic P:C ratios of 1:500–1:800 (Delwiche and Likens, 1977; Berner et al., 1993).

P is transported to oceans via rivers and wind, where the eolian fraction corresponds to 7–15% of the total preanthropogenic P freight (Graham and Duce, 1979; Compton et al., 2000). Rivers transport P as dissolved inorganic P (DIP), dissolved organic P (DOP) and in particulate forms (PIP, POP). PIP transport occurs in the form of detrital P and P absorbed onto iron oxyhydroxides and clay minerals (Meybeck, 1982, 1993; Compton et al., 2000; Seitzinger et al., 2005; Harrison et al., 2005). Recent estimates show that presently approximately 85% of the total P freight to the ocean is transported in particulate form (Beusen et al., 2005).

Once in the ocean, P enters a recycling loop between organic and inorganic forms, and only approximately 1% of the total amount of P used in primary productivity is permanently stored in the sedimentary reservoir per time unit. The P:C ratio in oceanic primary producers is significantly lower than that for terrestrial plants and amounts to 1:106–117 (Redfield, 1958; Anderson et al., 2001). The present-day residence time of oceanic P is estimated as between 10,000 and 17,000 years (Ruttenger, 1993, 2005; Colman and Holland, 2000).

Recent attempts to quantify P reservoirs and flux rates on a global scale have been published in Mackenzie et al. (1993), Compton et al. (2000), Harrison et al. (2005), Beusen et al. (2005), and Ruttenger (2005).

Phosphorus, microbes and life

The degree to which P may limit primary productivity in certain ecosystems is judged differently in the literature (Falkowski et al., 1992; Tyrrell, 1999). A vast array of

regional studies in which limiting capacities have been demonstrated exists. This appears especially the case in terrestrial, lacustrine, and near-shore oceanic environments, whereas open-ocean environments are often limited by nitrate or micronutrients such as iron (especially in high nutrient – low chlorophyll areas; Martin, 1991). Recently, a synergistic effect on primary productivity across most ecosystems has been proposed in case additions of nitrate and P are combined (Elser et al., 2007).

The above mentioned C:P ratios in primary producers predict that under P-limiting conditions, the addition of a single bioavailable P atom will lead to the photosynthetic transformation of more than 100 CO₂ molecules in oceans and 500–800 CO₂ molecules on the continent into organic carbon. This underlines the importance of P in environmental change.

Principal players in the transfer and transformation processes of P from solid, biounavailable forms into bioavailable forms and vice versa are microbes. They are involved in the solubilization and liberation of P from different substrata such as P-containing rocks and organic matter (Ehrlich, 1981; Krajewski et al., 1994), and they also play an active role in the remobilization of P in anoxic sedimentary environments and its reflux to primary producers (Gächter et al., 1988; Ingall et al., 1993; Van Cappellen and Ingall, 1994). Microbes also act in the reverse process – in the transfer of P into a solid mineral phase (in soils and sediments; Lucas and Prévôt, 1985; Soudry and Lewy, 1988; Krajewski et al., 1994; Schulz and Schulz, 2005).

Phosphogenesis and phosphorites

The precipitation of phosphate minerals in sediments is termed “phosphogenesis.” The principal mineral containing P in such environments is francolite ($\text{Ca}_{10-a-b}\text{Na}_a\text{Mg}_b(\text{PO}_4)_{6-x}(\text{CO}_3)_{x-y-z}(\text{CO}_3\text{F})_y(\text{SO}_4)_z\text{F}_2$; Jarvis et al., 1994). Phosphogenesis is a process which occurs in the first few top centimeters of marine and lacustrine sediments. Favorable to this process are the sufficient supply of reactive P and overall low sediment accumulation rates. The supply of P may be from internal sources such as the decomposition of trapped organic matter or the desorption of P from iron and manganese compounds, or external sources such as the supply from bottom waters across microbial mats at the sediment–water interface (Krajewski et al., 1994). The concentration of thus formed phosphates into phosphorites, i.e., P-enriched deposits which are sedimentary and generally of marine origin, is largely a mechanical affair, related to bottom-water currents and gravity-flow-related redeposition (Glenn et al., 1994a; Föllmi, 1996).

Presently, phosphorites form in a limited number of marine localities, which are almost all related to oceanic sites where the upwelling of deeper, P-enriched waters occurs (offshore Peru and Chile, Baja California, Namibia, SW India; Veeh et al., 1973; Burnett, 1977; Baturin, 1982; Jahnke et al., 1983; Garrison and Kastner,

1990; Glenn et al., 1994b). Recent phosphorite formation has also been reported from E Australia and Pacific atolls and guyots (O’Brien et al., 1990). Phosphogenesis and the formation of minor amounts of authigenic francolite are, however, phenomena in marine sedimentary environments which are more widespread than previously thought (Ruttenberg 1993, 2005; Delaney, 1998).

Phosphorus during the Earth’s history

Periods of formation of exploitable phosphorite deposits are unevenly spread throughout the Earth’s history. Important deposits are known from the following time windows (Cook and McElhinny, 1979): Precambrian–Cambrian boundary (China, Australia); Ordovician (Baltic countries); Permian (Wyoming, Idaho); Jurassic (Siberia, Mexico); late Cretaceous–Eocene (N Africa and Middle East countries); and Miocene (Florida). The unequal occurrence of P-enriched deposits in time suggests important fluctuations in the global P cycle, which are confirmed by other approximations of temporal behavior of the P cycle, such as a detailed analysis of P contents and variations therein in sedimentary cores retrieved during the Deep Sea Drilling Project and Ocean Drilling Program (Cook, 1984; Filippelli and Delaney, 1994; Föllmi, 1995). These temporal changes have been related to changes in global geochemical weathering output, which again is dependent on climate conditions and the creation of relief through orogenetic processes. Global change in the output of reactive, bioavailable P engendered important changes in the environment and life during the Earth’s history, such as shifts from oligotrophic to eutrophic ecosystems, accompanied by the widespread disappearance of reef and carbonate-platform systems and the enrollment of oceanic anoxic episodes (Hallock and Schlager, 1986; Hallock, 1987; Föllmi et al., 1994, 2006; Mort et al., 2007).

Phosphorus, eutrophication and anthropogenic impact

Recent estimates suggest that approximately 65% of the total DIP river flux to the ocean is anthropogenically derived (Harrison et al., 2005). The increased load of reactive P has a considerable impact on the environment in that the so-called dead zones without free oxygen develop and expand, and that wider zones with diminished oxygen contents are created, both in lakes as well as in marginal and open marine environments (Joos et al., 2003; Mee, 2006). Furthermore, shifts occur in the composition of ecosystems which may negatively affect oligotrophic ecosystems such as coral reefs (Hallock, 1987; Roberts et al., 2002). Some possible consequences of excessive P availability to the environment are (Föllmi, 1996):

- Development of dysaerobic to anaerobic mid-water and/or bottom-water conditions
- Severe damage to marine oligotrophic ecosystems such as coral reefs

- Limitation of marine and lacustrine benthic communities in dysaerobic bottom-water conditions
- Shorter feeding networks and simplified ecosystems
- Change to opportunistic phytoplankton species
- Increase in the intensity and frequency of “red tides,” i.e., toxic blooms of dinoflagellates and planktonic algae
- Toxic blooms of benthic cyanobacteria
- Higher rates of primary productivity
- Increased burial rates of lacustrine and marine organic matter

Summary

The strong interferences between the element P, life, and the environment render this element of particular interest. From the certainly biased view of a geologist, important recent contributions and potential pathways of future research relate to the following topics:

- The extend of the capacity of P as a limiting nutrient
- Precise quantifications of reservoir and flux rates and of residence times
- Possible interferences between present-day anthropogenic change in the P cycle and the environment
- Coupling between the P cycle and other cycles of biophile elements and molecules
- Weathering of P-containing rocks and the release of P to the biosphere
- Pathways and conditions leading to P mineralization and accumulation in sedimentary environments
- Temporal changes in the global P cycle during the Earth's history and their impact on the paleoenvironment.

Definition

Process used by photoautotrophic organisms to combine carbon dioxide into carbohydrates utilizing the energy of sunlight.

Introduction

Photosynthesis is the most important biological process on Earth since it provides the reduced carbon and the molecular oxygen which are essential for almost all life on this planet. It is the basic metabolic reaction of organisms that contain chlorophyll where energy rich organic compounds are synthesized using the energy of sunlight. During the light-dependent reaction, the energy of the sunlight is converted into chemical energy with the help of light absorbing pigments, usually chlorophyll. This chemical energy is then used in a light-independent reaction to fix carbon dioxide and to produce carbohydrates.

The net equation of photosynthesis is:

Oxygenic photosynthesis which releases oxygen is found in green plants and cyanobacteria while anoxygenic photosynthesis is found in purple bacteria, green sulfur bacteria, green nonsulfur bacteria, and heliobacteria.

Photosynthesis is almost as old as life itself. Oxygenic photosynthesis has evolved from anoxygenic photosynthesis, however there are different opinions on when this happened. Oxygenic photosynthesis was responsible for the Great Oxygenation Event about 2.300 million years ago when oxygen was released into the Earth's atmosphere, but it probably evolved at least several hundred

million years earlier (see Björn and Govindjee, 2009 for review).

Oxygenic photosynthesis

During the light-dependent reactions of oxygenic photosynthesis, light energy is absorbed by chlorophyll and converted to chemical energy in the form of ATP (adenosine triphosphate) and $\text{NADPH} + \text{H}^+$ (nicotinamide adenine dinucleotide triphosphate) which can then be used in the light-independent reactions to produce sugars from carbon dioxide. During the light reactions oxygen is released as a by-product (Figure 1a).

The net equation for the light reactions of the oxygenic photosynthesis is:

Plants and cyanobacteria, the organisms using oxygenic photosynthesis, contain two photosystems: photosystem I (PSI) and photosystem II (PSII). Each photosystem is surrounded by a light harvesting complex comprising a large number of pigments, mainly chlorophylls and carotenoids. The reaction center of PSII contains a pair of chlorophyll *a* molecules with an absorption maximum of 680 nm wavelength and is therefore called P680, while the chlorophyll *a* of PSI (P700) has an absorption maximum of 700 nm. In cyanobacteria, the photosystems are situated in the plasma membrane which is often folded to stacks called thylakoids. In plants, the thylakoid membrane can be found in the chloroplasts which are derived from cyanobacteria.

When sunlight strikes the light-harvesting complex of PSII, a photon excites an electron of a pigment molecule and the energy is passed on to the next pigment molecule until it reaches the reaction-center of PSII where an electron of the P680 pair of chlorophyll molecules is excited to a higher energy state. This electron is transferred to pheophytin, the primary electron acceptor, through charge separation. In the oxygen evolving complex, water is split into two electrons, two hydrogen ions and an oxygen atom. The electrons fill the gap in the P680 while the oxygen atom combines with another oxygen atom to form dioxygen. Meanwhile, the electron from the pheophytin is transported down an electron transport chain consisting of the electron carrier plastoquinone (PQ), a cytochrome complex (Cyt_{b_6}), and the protein plastocyanin (PC). A proton gradient, which is built up when electrons pass through the electron transport chain in thermodynamically favorable direction, is used by the enzyme ATP-synthase for ATP-synthesis via photophosphorylation, where ATP is generated by adding a phosphate group to ADP. In the reaction-center of PSI, an electron of P700 pair of chlorophyll is excited after light energy is transferred from the light-harvesting complex of this photosystem. This electron is passed on to the primary electron acceptor, a special chlorophyll molecule, while the P700 now

Process used by photoautotrophic organisms to combine carbon dioxide into carbohydrates utilizing the energy of sunlight.

Introduction

Photosynthesis is the most important biological process on Earth since it provides the reduced carbon and the molecular oxygen which are essential for almost all life on this planet. It is the basic metabolic reaction of organisms that contain chlorophyll where energy rich organic compounds are synthesized using the energy of sunlight. During the light-dependent reaction, the energy of the sunlight is converted into chemical energy with the help of light absorbing pigments, usually chlorophyll. This chemical energy is then used in a light-independent reaction to fix carbon dioxide and to produce carbohydrates.

The net equation of photosynthesis is:

Oxygenic photosynthesis which releases oxygen is found in green plants and cyanobacteria while anoxygenic photosynthesis is found in purple bacteria, green sulfur bacteria, green nonsulfur bacteria, and heliobacteria.

Photosynthesis is almost as old as life itself. Oxygenic photosynthesis has evolved from anoxygenic photosynthesis, however there are different opinions on when this happened. Oxygenic photosynthesis was responsible for the Great Oxygenation Event about 2.300 million years ago when oxygen was released into the Earth's atmosphere, but it probably evolved at least several hundred

million years earlier (see Björn and Govindjee, 2009 for review).

Oxygenic photosynthesis

During the light-dependent reactions of oxygenic photosynthesis, light energy is absorbed by chlorophyll and converted to chemical energy in the form of ATP (adenosine triphosphate) and $\text{NADPH} + \text{H}^+$ (nicotinamide adenine dinucleotide triphosphate) which can then be used in the light-independent reactions to produce sugars from carbon dioxide. During the light reactions oxygen is released as a by-product (Figure 1a).

The net equation for the light reactions of the oxygenic photosynthesis is:

Plants and cyanobacteria, the organisms using oxygenic photosynthesis, contain two photosystems: photosystem I (PSI) and photosystem II (PSII). Each photosystem is surrounded by a light harvesting complex comprising a large number of pigments, mainly chlorophylls and carotenoids. The reaction center of PSII contains a pair of chlorophyll *a* molecules with an absorption maximum of 680 nm wavelength and is therefore called P680, while the chlorophyll *a* of PSI (P700) has an absorption maximum of 700 nm. In cyanobacteria, the photosystems are situated in the plasma membrane which is often folded to stacks called thylakoids. In plants, the thylakoid membrane can be found in the chloroplasts which are derived from cyanobacteria.

When sunlight strikes the light-harvesting complex of PSII, a photon excites an electron of a pigment molecule and the energy is passed on to the next pigment molecule until it reaches the reaction-center of PSII where an electron of the P680 pair of chlorophyll molecules is excited to a higher energy state. This electron is transferred to pheophytin, the primary electron acceptor, through charge separation. In the oxygen evolving complex, water is split into two electrons, two hydrogen ions and an oxygen atom. The electrons fill the gap in the P680 while the oxygen atom combines with another oxygen atom to form dioxygen. Meanwhile, the electron from the pheophytin is transported down an electron transport chain consisting of the electron carrier plastoquinone (PQ), a cytochrome complex (Cyt_{b_6}), and the protein plastocyanin (PC). A proton gradient, which is built up when electrons pass through the electron transport chain in thermodynamically favorable direction, is used by the enzyme ATP-synthase for ATP-synthesis via photophosphorylation, where ATP is generated by adding a phosphate group to ADP. In the reaction-center of PSI, an electron of P700 pair of chlorophyll is excited after light energy is transferred from the light-harvesting complex of this photosystem. This electron is passed on to the primary electron acceptor, a special chlorophyll molecule, while the P700 now

Photosynthesis, Figure 1 Oxygenic photosynthesis. (a) Simplified view of the thylakoid membrane of a chloroplast. The *dashed line* represents the electron flow through the photosystems PSII and PSI during the light reactions. *TM* thylakoid membrane, *STR* stroma, *TL* thylakoid lumen, *OEC* oxygen evolving complex, *PQ* Plastoquinone, *Cyt $_{bf}$* Cytochrome b_f , *PC* Plastocyanin, *Fd* Ferredoxin, *FNR* Ferredoxin-NADP $^+$ -oxidoreductase. (b) Calvin cycle. The regeneration steps from Glyceraldehyde-3-phosphate to Ribulose-1,5-bisphosphate are not shown.

accepts the electron that reaches the end of the electron transport chain of PSII. The excited electron of PSI is then transferred along a second electron transport chain and is then used to reduce NADP $^+$ to NADPH + H^+ . This electron transfer requires ferredoxin (Fd) and ferredoxin-NADP $^+$ -oxidoreductase (FNR; for more details on photosystems and light reactions, see, e.g., Whitmarsh and Govindjee, 1999; Lawlor, 2001; Renger, 2010).

The Calvin cycle uses the energy of ATP and the reducing power of NADPH + H^+ which are produced during the light reactions to convert carbon dioxide into carbohydrates. It is independent from sunlight and therefore often called dark reaction. The Calvin cycle takes place in the stroma of the chloroplasts of plants and in the cytoplasm of cyanobacteria.

The net equation for the light-independent reactions of the oxygenic photosynthesis is:

Carbon dioxide enters the Calvin cycle during carbon fixation, a process which is catalyzed by ribulose biphosphate carboxylase (rubisco). Each molecule of carbon dioxide is attached to a molecule of the five-carbon sugar ribulose-1,5-bisphosphate. The resulting unstable six-carbon sugar splits in two 3-phosphoglycerate molecules which then become 1,3-bisphosphoglycerate, receiving phosphate groups from ATP. With the help of NADPH + H^+ , each molecule of 1,3-bisphosphoglycerate

is then reduced to glyceraldehyde-3-phosphate which can be used to form glucose or other organic compounds. However, only one of six glyceraldehyde-3-phosphate molecules leaves the Calvin cycle while the rest is used for the regeneration of the carbon dioxide acceptor ribulose-1,5-bisphosphate which requires more ATP (Figure 1b; for more details on Calvin cycle, see, e.g., Lawlor, 2001; Heldt, 2003).

Anoxygenic photosynthesis

Anoxygenic photosynthesis, which can be found in purple bacteria, green sulfur bacteria, green non-sulfur bacteria, and heliobacteria, differs from oxygenic photosynthesis in that it requires only one photosystem and, since no splitting of water occurs, no oxygen is produced. The photosystem used by purple bacteria and green nonsulfur bacteria is similar to the PSII of plants and cyanobacteria, but contains bacteriochlorophyll instead of chlorophyll. The electron transport is cyclic since the electrons return to the reaction center after passing through a series of electron carriers. The product of the electron transport in the photosystem is ATP. Purple bacteria and green nonsulfur bacteria must oxidize inorganic or organic compounds such as H_2S , H_2 , succinate, or malate to provide the reduction potential necessary for carbon fixation. By using these compounds as electron donors, NAD^+ (nicotinamide adenine dinucleotide) is reduced to $\text{NADH} + \text{H}^+$ in a process called reverse electron transport. Purple bacteria use the Calvin cycle to fix carbon dioxide while green non-sulfur bacteria use a special process called 3-hydroxypropionate pathway.

Green sulfur bacteria and heliobacteria contain a photosystem that resembles the PSI of oxygenic photosynthetic organisms. It has a cyclic electron flow, but here NAD^+ can be reduced directly. Green sulfur bacteria use the reverse Krebs cycle to fix carbon dioxide, while heliobacteria are photoorganotrophs (for more details on anoxygenic photosynthesis, see, e.g., Whitmarsh and Govindjee, 1999; Madigan et al., 2009).

Summary

The light reactions of photosynthesis use the energy of sunlight to provide chemical energy and reducing power in the form of ATP and $\text{NADPH} + \text{H}^+$, respectively, which can then be used in the light-independent reactions to fix carbon dioxide and to convert it into carbohydrates. During the oxygenic photosynthesis of plants and cyanobacteria, water is split and dioxygen is released, whereas anoxygenic photosynthetic organisms such as purple bacteria, green sulfur bacteria, green nonsulfur bacteria, and heliobacteria do not produce oxygen.

Barophilic bacteria

Definition and introduction

Modern deep-sea microbiology was born in the twentieth century, thanks mainly to the efforts of Claude E. ZoBell, Frank H. Johnson, Richard Y. Morita, Holger W. Jannasch, A. Aristides Yayanos, Koki Horikoshi, and others. ZoBell and coworkers were the first group to study the effect of hydrostatic pressure on microbial activity in the deep sea (ZoBell and Johnson, 1949). They coined the term “barophile” to describe bacteria that have “a requirement for increased pressure for growth, or by increased growth at pressures higher than atmospheric pressure” (Jannasch and Taylor, 1984). Pelagic sediments taken from the Philippine Trench at more than 10,000 m (>100 MPa) contained 10^4 to 10^5 cells of viable bacteria g^{-1} wet weight of various physiological types (ZoBell and Morita, 1956) including nitrate reducers, sulfate reducers, and ammonifiers. Most of these organisms were obligate barophiles, unable to grow at atmospheric pressure (0.1 MPa).

Yayanos and his group were the first to successfully isolate a pressure-adapted bacterium (strain CNPT3) from amphipods collected from the deep sea at 5,700 m in the Pacific (Dietz and Yayanos, 1978). Strain MT41 was probably the first recognized obligate barophile isolated from a decomposing amphipod, *Hirondella gigas*, from a depth of 10,476 m of the Mariana Trench (Yayanos

Interstitial waters

Definition

The term *pore water* refers to the water contained in the interstices/pore space of aquatic sediments.

Introduction

Extracting pore waters and analyzing various dissolved constituents is a central approach in marine sediment

geochemistry, biogeochemistry, and geo(micro)biology. The ensuing pore-water concentration-depth profiles are used (a) to characterize the geochemical environment and redox zonation of aquatic sediments (Froelich et al., 1979; Berner, 1981; Postma and Jakobsen, 1996), (b) to infer and identify early diagenetic and biogeochemical processes by compounds which are either consumed or released by the particular reaction (Reeburgh, 1969; Froelich et al., 1979), (c) to calculate diffusive fluxes of dissolved constituents (Hensen et al., 2006; Zabel and Hensen, 2006), and (d) to model reaction and turnover rates of biogeochemical and diagenetic processes – including mineral dissolution and precipitation (Berner, 1980; Van Cappellen and Wang, 1995; Boudreau, 1996). Furthermore, pore-water profiles are applied to quantify the abundance of gas hydrates in marine deposits (Ussler and Paull, 2001; Bohrmann and Torres, 2006) and to study subsurface fluid flow (Saffer and Scretton, 2003).

Pore-water profiles evolve as a consequence of the complex interplay between successive microbial degradation of organic matter by various electron acceptors and a broad spectrum of secondary diagenetic reactions on the one hand and different transport processes (diffusion, advection, bioturbation, and bioirrigation) on the other hand. Due to the close coupling between geochemistry and microbiology, concentration-depth profiles of dissolved chemical species often point to “new” – i.e., to date unknown – biogeochemical processes and metabolic pathways and pave the way for the discovery of novel microorganisms or consortia of microbes which mediate the particular reactions. A well-known example is the process of anaerobic oxidation of methane by sulfate (AOM) which was already postulated to occur on the base of pore-water profiles in the late 1960s (Reeburgh, 1969). Only about 30 years later, new and advanced techniques in molecular biology ultimately were able to prove the existence of microbial consortia of archaea and sulfate-reducing bacteria mediating this process (Boetius et al., 2000; Orphan et al., 2001).

Extraction and analyses of pore waters

The classical ways of extracting pore waters are (a) by squeezers where pressure is applied either by an inert gas (e.g., nitrogen, argon) or with a hydraulic press, or (b) by centrifuging and subsequent decanting (Gieskes et al., 1991; Schlüter, 1990; De Lange et al., 1992; for a review see Schulz, 2006, and references therein). In recent years, a new technique for a rapid and more or less nondestructive collection of pore waters from marine sediments has been developed and established – the so-called rhizon sampling (Seeberg-Elverfeldt et al., 2005; Dickens et al., 2007). Rhizon samplers are thin tubes of hydrophilic porous polymer which have a minimum pore size of 0.1 µm. They are inserted into the sediment and are connected to either vacuum vials, spring-loaded syringes, or operated with peristaltic pumps which allow to

extract interstitial fluids without seriously altering the sediment structure.

Due to the often limited amount of pore water extractable – on average only a few milliliters – the analyses of individual dissolved constituents have to be performed on small sample volumes. Therefore, common methods of seawater analyses (Grasshoff et al., 1999) have been modified accordingly to allow the determination of the concentrations of nutrients and other dissolved chemical species from milliliter to submilliliter sample aliquots. A detailed overview of the techniques and instruments used in pore-water retrieval and analyses is available on <http://www.geochemie.uni-bremen.de/koelling/index.html>. For a concise introduction into the interpretation of pore-water profiles as well as the calculation of diffusive fluxes of dissolved pore-water constituents please refer to Schulz (2006).

Besides the extraction and analysis of pore water, chemical gradients at the sediment/water interface as well as in other environments characterized by a highly condensed geochemical zonation are generally determined by means of microsensors. Typical applications comprise the use of microelectrodes for oxygen, pH, and hydrogen sulfide as well as fiber-optic sensors – i.e., optodes and planar optodes – for oxygen to study and quantify transport processes as well as biogeochemical reactions in surface sediments (Archer et al., 1989; Jørgensen, 2001; Kühl and Revsbech, 2001; Wenzhöfer et al., 2001). The advantage of microelectrodes and optodes compared to the above-described pore-water sampling approaches is that they are sufficiently small to resolve steep chemical gradients and thus allow to accurately measure concentration differences and to calculate diffusive fluxes and model reaction rates. Determining chemical gradients at a high spatial resolution is of prime importance in geo(micro)biology in order to identify microenvironments and other small-scale geochemical heterogeneities as well as to determine steep concentration gradients as they typically exist in and across microbial mats and biofilms as well as at and around mineral and rock surfaces (De Beer and Kühl, 2001; Kühl, 2005; Krüger et al., 2008).

Biogeochemical processes and redox zonation

Particulate organic matter that is deposited on the seafloor is attacked by a broad range of organisms that all contribute to its degradation and gradual mineralization. At the sediment surface, macrofauna play a particularly important role by mechanically disintegrating the detritus and mixing and irrigating the upper sediment layer so that organic material becomes repeatedly exposed to oxygen. After the microbial fermentation/depolymerization of larger organic compounds into smaller organic molecules like, e.g., acetate, formate, and hydrogen microorganisms utilize a suite of external oxidants (electron acceptors) to mineralize these fermentation products (Froelich et al., 1979; Jørgensen, 2006). The different dissolved and solid

phase oxidants are used in the following order of decreasing energy yield: oxygen, nitrate, manganese (oxihydr)oxides, iron (oxihydr)oxides, and sulfate (Froelich et al., 1979). This sequence of oxidants used in the degradation of organic matter as well as the manifold secondary biotic and abiotic redox processes lead to the establishment of a typical redox or biogeochemical zonation (Froelich et al., 1979; Berner, 1981) which is shown schematically in Figure 1 together with the characteristic concentration-depth profiles of dissolved pore-water constituents. Besides marine sediments a similar segregation of electron-accepting processes in separate zones during the degradation of organic material is also found in lacustrine deposits as well as in groundwater environments.

It should be emphasized that the scheme depicted in Figure 1 is of course simplified and that in natural aquatic sediments the different redox processes in the degradation of organic matter can considerably overlap or the redox zones can even be reversed depending on the availability, abundance, and reactivity of the particular electron acceptors (Postma and Jakobsen, 1996). In any case, the evolving biogeochemical zonation – being itself significantly shaped by microbial metabolism (and activity of macrofauna at the sediment surface) – at the same time exerts a strong control on a broad spectrum of processes like (a) colonization by macro- and microorganisms, (b) different degrees of selective degradation and preservation of organic compounds (including paleoceanographic proxies) under oxic, anoxic or sulfidic conditions (Versteegh and Zonneveld, 2000), as well as (c) processes of mineral dissolution and precipitation (Torres et al., 1996; Peckmann et al., 2001; Kasten et al., 2003).

Mathematical modeling of pore-water profiles

Due to the fact that pore-water profiles are influenced by the sum of all reactions, process rates directly calculated from pore-water profiles may be highly inaccurate and always represent *net* rates. The development of numerical models that couple transport processes and (bio)geochemical reactions has therefore been a major advance that allows to more comprehensively interpret sediment pore-water profiles (Berner, 1980; Van Cappellen and Wang, 1995, 1996; Boudreau, 1996, 1997; Soetaert et al., 1996). Such early diagenetic reaction-transport models have been applied on various sediment depth scales, reaching from the simulation of processes close to the sediment surface like calcite dissolution and the cycling of iron and manganese (Van Cappellen and Wang, 1995, 1996; Adler et al., 2001; Pfeifer et al., 2002; Jourabchi et al., 2008) down to reactions occurring at and below the sulfate/methane transition zone in more deeply buried deposits (Riedinger et al., 2005; Wallmann et al., 2006). Reaction-transport models generally include a network of primary and secondary redox reactions as well as different transport processes and are fitted to the measured pore-water profiles. In this

Pore Waters, Figure 1 Schematic representation of the biogeochemical zonation in marine sediments. The names of the main zones were proposed by Froelich et al. (1979) and Berner (1981, in parenthesis). The depth scale is quasi-logarithmic; the exact depths, however, vary strongly and increase from the shelf to the deep sea. The pore-water chemistry shows relevant dissolved species. Peak heights and concentration scales are arbitrary. The chemical profiles reflect the depth sequence of the dominant mineralization processes through which organic matter is oxidized to CO_2 . (Modified from Froelich et al., 1979; Jørgensen and Kasten, 2006, with permission.)

way, reaction rates can be obtained which can, however, differ from *gross* reactions rates.

In the case of sulfate reduction, *gross* rates can be measured by experimental incubation of sediment samples after addition of radioactively labeled sulfate ($^{35}SO_4^{2-}$) [for reviews see Jørgensen (2006) and Jørgensen and Kasten (2006)]. While this experimental technique is optimal to determine process rates in shallow and highly dynamic surface sediments, a modeling approach is generally preferred in more deeply buried sediments (Jørgensen, 2006).

Conclusion

Pore-water profiles represent a powerful tool to determine the variations in redox and biogeochemical conditions over sediment depth which is a prerequisite for the identification and quantification of early diagenetic influences on the geological record and for an accurate interpretation of paleoceanographic proxies. Furthermore, chemical gradients in the pore water of aquatic sediments are used to infer and identify biogeochemical reactions and to model process rates. However, it should be emphasized that due to the fact that pore-water profiles result from the

interactive effects of production and consumption of multiple species during biogeochemical processes certain reaction products are not always detectable in pore water, although the particular reaction proceeds at high rates. For the same reason care has to be taken when process rates are derived from modeling of pore-water profiles. In general, numerical modeling has its strength in deep sediments while experimental measurements are more suitable to determine *gross* process rates in surface sediments.

PROTOZOA (HETEROTROPH, EUKARYOTIC)

Jens Boenigk
 Austrian Academy of Sciences, Mondsee, Austria

Synonyms

Protist (pro parte); Protoctista (pro parte)

Definition

Protozoa (historical) Animals that can be reduced to the status of one cell.

Protozoa (modern) All eukaryotes after exclusion of the derived kingdoms such as Animalia, Fungi, Plantae, and Chromista.

Introduction

Protozoa are a loose grouping of organisms with similar (usually unicellular) organization and heterotrophic mode of nutrition. They are found in most soils, fresh water, and oceans. As components of the micro- and meiofauna, Protozoa are important consumers of bacteria and an important food source for microinvertebrates. While most are solitary individuals, various colonial forms exist. The taxonomic relationships of protozoans to one another and to other protists continue to be revised. Most are free-living, but some are commensalistic, mutualistic, or parasitic. Pathogenic Protozoa include species of

Plasmodium, the cause of human malaria, *Trypanosoma gambiense*, the cause of African trypanosomiasis, and *Entamoeba histolytica*, the cause of amebic dysentery. The smallest known protozoans are tiny blood parasites less than 2 microns long; the largest may be 16 mm long and visible to the naked eye. The cells show all typical features of a eukaryotic cell. Protozoan shapes vary, but all share such eukaryotic features as lipid–protein membranes and membrane-enclosed vacuoles and organelles. Ultrastructure as well as biochemical cell composition varies a lot due to the broad diversity of these organisms. They also show wide variation in modes of movement, nutrition, and reproduction. Reproduction is usually asexual, occurring mostly by cell division, or binary fission; some forms reproduce asexually by budding or by the formation of spores (reproductive cells that give rise to a new organism without fertilization). In several groups sexual reproduction also occurs.

The number of protozoan species is controversial. Only less than 10% of the species are described and the theoretical basis, that is, the species concept, is also controversial. The most widely used biological species concept is hardly applicable to Protozoa as reproductive isolation, which is the basis of the biological species concept, is rarely investigated for most taxa. In practice, protozoan species were largely defined based on morphological characteristics. However, the degree of molecular similarity between sexual conspecifics is increasingly used as a yardstick for asexual ones from comparable evolutionary lineages. For an increasing number of morphologically described species (morphospecies) molecular data demonstrate an insufficient taxon resolution. Consequently, the species number estimates are increasing. Current estimates of species numbers range from several hundreds of thousands to several million with around 70,000 described species. Further, environmental molecular surveys mostly based on the 18S rRNA gene demonstrate that only a minority of sequences is known and the species number estimates based on morphological analyses may underestimate the diversity by orders of magnitude.

Megasystematics and nomenclature

During the period of protistology, that is, from the first descriptions of microorganisms by van Leeuwenhoek in 1674 to date, the classification of Protozoa changed several times depending on the available methodology. Motility was the main or only criterion for the first observers to place these organisms within the animal kingdom; any signs of internal organization were also considered sufficient proof of the animal nature of these organisms. From the mid-nineteenth century onward, the mode of nutrition, that is, heterotrophy and specifically particulate food uptake versus autotrophy, became the dominating criterion in differentiating Protozoa (animals) from Protophyta (plants). The systematic position of the Protozoa and related organisms remained and still remains unclear for many lineages. In consequence, alternative concepts arose, which shall be briefly introduced, starting with the historic context of the

EARLY PRECAMBRIAN EUKARYOTES

Joachim Reitner
University of Göttingen, Göttingen, Germany

Definition

Eukaryotes are probably the result of endosymbiosis, and basically three types exist. The basic ones are the simplest eukaryotic cells with a nucleus only (*Giardia*) (Graczk, 2005). Secondly, protists have mitochondria, which have been proposed to have an alpha-proteobacterial origin (Sagan (Margulis), 1967). Finally, beside mitochondria, cells of eukaryotic algae contain chloroplasts, former single-celled cyanobacteria achieved via endosymbiosis (Mereschkowsky, 1905; Wallin, 1920; Sagan (Margulis), 1967). The geological record of protists begins long before the Ediacaran vendobionts. Possibly stem group protists were found in ca. 3 Ga-old rocks (Javaux et al., 2010). Within the Late Mesoproterozoic rocks, the divergence of major eukaryotic clades is observed. Beside the fossil record of early eukaryotes, related biomarkers (steranes) were found in up to 2.7 Ga-old rocks, which may support the early origin of eukaryotes before the Great Oxidation Event (Brocks et al., 1999; Brocks et al., 2003a, b). However, the syngeneity of the biomarkers used for the interpretation has recently been questioned (Rasmussen et al., 2008) and the first appearance of eukaryotic biomarkers is still disputed (Brocks

et al., 1999; George et al., 2008; Rasmussen et al., 2008; Waldbauer et al., 2009).

The oldest known single-celled eukaryotes are acritarchs, probably ancestors of dinoflagellates. Acritarchs played a significant role in Proterozoic oceans, and the first record comes from the 3.2 Ga-old Moodies Group of South Africa (Javaux et al., 2010). This finding is surprising, since eukaryotic metabolisms normally need oxygen, and the Great Oxidation Event took place about 700 My later, between 2.32 and 2.45 Ga. A similar discrepancy emerged from the first appearance of eukaryotic biomarkers in 2.7 Ga-old rocks (Brocks et al., 1999). Although often controversially debated, biomarker records may give excellent indications to the diversification of major phylogenetic clades. For instance, the distribution of 24-isopropylcholestane revealed a high abundance of (demo-)sponges in the Cryogenian (McCaffrey et al., 1994; Love et al., 2009), thus suggesting sufficient oxygen in shelf regions already 100 My prior to the Cambrian explosion. Furthermore, early Precambrian eukaryotic life is not only indicated by biomarker findings. In some diagenetically early silicified stromatolites, well-preserved eukaryotic cells have been described. The best material is known from the 1.88 Gy-old Gunflint Chert (Ontario, Canada) (Fralick et al., 2002; Awramik and Barghoorn, 1977). *Eosphaera tyleri* from these cherts is probably an eukaryotic cell (Kazmierczak, 1979). Beside the single-celled eukaryotes, few larger fossils which are most likely multicellular organisms are known, such as *Grypania spiralis* from the Mesoproterozoic Gaoyuzhuang Formation (China) and disk-shaped centimeter-sized organisms like *Chuaria* (Knoll et al., 2006).

In the Cryogenian and Ediacaran, the diversity of eukaryotes, including fungi and lichens, increased significantly. It is obvious that the increase of diversity and size

is related with the Snowball Earth scenarios and increase of oxygen in the atmosphere.

EDIACARAN BIOTA

Dmitriy Grazhdankin
 Russian Academy of Sciences, Novosibirsk, Russia

Definition

Ediacaran period: An interval in the history of earth after the Marinoan/Varanger glaciation of the Neoproterozoic Era (see Chapter *Snowball Earth*), but before the Cambrian radiations. This interval marks the introduction of complex macroscopic organisms, leading to a revolution in the structure and evolution of marine paleocommunities, including the establishment of multi-level trophic structures, coevolutionary predator–prey interactions and infauunal activity.

Ediacaran biota: A highly distinctive assemblage of Ediacaran-age macroscopic organisms preserved as casts and moulds in siliciclastic, volcanoclastic, and carbonate sediments.

Introduction

Ediacaran biota is a heterogeneous assemblage representing the earliest known communities of macroscopic organisms. Diverse Ediacaran fossil assemblages are coeval with the earliest phosphatized metazoan embryos (Xiao et al., 1998; but see Bailey et al., 2007; Xiao et al., 2007), the earliest undisputed traces of metazoan activities (Jensen, 2003), and the time of eumetazoan crown-group divergence estimated by some (but not all) molecular clocks (Peterson and Butterfield, 2005). Nonetheless, placing the Ediacaran morphologies into a metazoan phylogeny has been an enduring challenge to paleobiologists (Gehling, 1991; Fedonkin, 1992; Jenkins,

PROTOZOA (HETEROTROPH, EUKARYOTIC)

Jens Boenigk
 Austrian Academy of Sciences, Mondsee, Austria

Synonyms

Protist (pro parte); Protoctista (pro parte)

Definition

Protozoa (historical) Animals that can be reduced to the status of one cell.

Protozoa (modern) All eukaryotes after exclusion of the derived kingdoms such as Animalia, Fungi, Plantae, and Chromista.

Introduction

Protozoa are a loose grouping of organisms with similar (usually unicellular) organization and heterotrophic mode of nutrition. They are found in most soils, fresh water, and oceans. As components of the micro- and meiofauna, Protozoa are important consumers of bacteria and an important food source for microinvertebrates. While most are solitary individuals, various colonial forms exist. The taxonomic relationships of protozoans to one another and to other protists continue to be revised. Most are free-living, but some are commensalistic, mutualistic, or parasitic. Pathogenic Protozoa include species of

Plasmodium, the cause of human malaria, *Trypanosoma gambiense*, the cause of African trypanosomiasis, and *Entamoeba histolytica*, the cause of amebic dysentery. The smallest known protozoans are tiny blood parasites less than 2 microns long; the largest may be 16 mm long and visible to the naked eye. The cells show all typical features of a eukaryotic cell. Protozoan shapes vary, but all share such eukaryotic features as lipid–protein membranes and membrane-enclosed vacuoles and organelles. Ultrastructure as well as biochemical cell composition varies a lot due to the broad diversity of these organisms. They also show wide variation in modes of movement, nutrition, and reproduction. Reproduction is usually asexual, occurring mostly by cell division, or binary fission; some forms reproduce asexually by budding or by the formation of spores (reproductive cells that give rise to a new organism without fertilization). In several groups sexual reproduction also occurs.

The number of protozoan species is controversial. Only less than 10% of the species are described and the theoretical basis, that is, the species concept, is also controversial. The most widely used biological species concept is hardly applicable to Protozoa as reproductive isolation, which is the basis of the biological species concept, is rarely investigated for most taxa. In practice, protozoan species were largely defined based on morphological characteristics. However, the degree of molecular similarity between sexual conspecifics is increasingly used as a yardstick for asexual ones from comparable evolutionary lineages. For an increasing number of morphologically described species (morphospecies) molecular data demonstrate an insufficient taxon resolution. Consequently, the species number estimates are increasing. Current estimates of species numbers range from several hundreds of thousands to several million with around 70,000 described species. Further, environmental molecular surveys mostly based on the 18S rRNA gene demonstrate that only a minority of sequences is known and the species number estimates based on morphological analyses may underestimate the diversity by orders of magnitude.

Megasystematics and nomenclature

During the period of protistology, that is, from the first descriptions of microorganisms by van Leeuwenhoek in 1674 to date, the classification of Protozoa changed several times depending on the available methodology. Motility was the main or only criterion for the first observers to place these organisms within the animal kingdom; any signs of internal organization were also considered sufficient proof of the animal nature of these organisms. From the mid-nineteenth century onward, the mode of nutrition, that is, heterotrophy and specifically particulate food uptake versus autotrophy, became the dominating criterion in differentiating Protozoa (animals) from Protophyta (plants). The systematic position of the Protozoa and related organisms remained and still remains unclear for many lineages. In consequence, alternative concepts arose, which shall be briefly introduced, starting with the historic context of the

definitions of the terms Protozoa, Protista, and Protoctista, which are often synonymously used despite the different conceptual background (Scarmadella, 1999).

Based on the German term “Urthiere” (von Oken, 1805) Georg August Goldfuß introduced the class **Protozoa** (first, or early animals) in 1820 for a class of organisms within Kingdom Animalia that consisted of Infusoria (called ciliates today), Lithozoa (corals), Phytozoa (e.g., Cryptomonas), and Medusinae. The term implies that these organisms are animals or animal-like and have been separated from the plant-like protophytes. After the formulation of the cell theory, Carl Theodor von Siebold defined in 1845 the Protozoa as animals that can be reduced to the status of a cell and subdivided his Phylum into the classes Infusoria (ciliates) and Rhizopoda (amoebae, foraminifera). In 1858, Richard Owen referred to this grouping as Kingdom Protozoa and defined the group by their lack of a certain number of characters, or “superadditions,” of true plants and animals. Since molecular systematics increasingly demonstrates a close relationship between phototrophic and phagotrophic microeukaryotes the term Protozoa was increasingly replaced by Protista (see below). Still, the term Protozoa is used by some scientists as a paraphyletic basal kingdom, that is, comprising the Amoebozoa, Choanoflagellates, Rhizaria, Excavata, and Alveolata (Cavalier-Smith, 2003).

Based on the problems to distinguish the Protozoa from the Protophyta, John Hogg proposed the term **Protoctista** in 1861 as a grouping of organisms having the common characters of both plants and animals. Hogg’s term “Protoctista” was expressive of organisms that came first in evolutionary time. What is significant in Hogg’s depiction of the Protoctista is that plants and animals share a common ancestry from the Protoctista. Protoctista are those microscopic and macroscopic eukaryotes that remain after exclusion of all animals developing from a blastula, all plants developing from embryonic stages, and all higher fungi without a flagellate stage in their life cycles (Margulis et al., 1990).

Agreeing with the erratic separation of Protozoa and Protophyta but disagreeing with Hogg’s view of Protoctista being the evolutionary first beings, Haeckel considered that these organisms evolved independent of the lineages of the animal and plant kingdoms. In 1866, he proposed the term **Protista** as a boundary kingdom intermediate between the animal and vegetable kingdoms containing organisms neither animals nor plants. According to the various definitions given by Haeckel himself, bacteria were Protista as well but Infusoria (ciliates) were placed in Kingdom Animalia as he (and other investigators) considered them multicellular animals. In the modern sense, the Protista embraces all eukaryotes that lack tissues, that is, a loose grouping of 30 or 40 disparate phyla with diverse combinations of trophic modes, mechanisms of motility, cell coverings, and life cycles.

In an ecological or functional context, Protozoa ($\approx$ phagotrophic protists) still is a meaningful term but due to the conceptual problems increasingly replaced by

the term protists or by applying narrower functional groups such as heterotrophic flagellates, amoebae, and ciliates. The major lineages of phagotrophic protists are (see Adl et al., 2005):

- Amoebozoa L  he, 1913, emend. Cavalier-Smith, 1998, that is, organisms with amoeboid locomotion generally with noneruptive morphologically variable pseudopodia (lobopodia). Flagellate stages may sometimes occur usually with a single flagellum. Note that several groups of amoeboid protists do not belong to the Amoebozoa.
- Choanomonada Kent, 1880 (choanoflagellates), that is, phagotrophic with collar of microvilli around a single flagellum. This group is traditionally divided into three groups based on the presence or absence of a cellulose theca or lorica of siliceous strips.
- Rhizaria Cavalier-Smith, 2002, that is, cells with fine pseudopodia (filopodia) varying as simple, branching, anastomosing, or supported by microtubules (axopodia). This group includes ecologically important benthic and soil protists such as the usually amoeboid and/or biflagellated Cercozoa and well as the palaeoecologically important Foraminifera and Radiolaria.
- Alveolata Cavalier-Smith, 1991, that is, protists with cortical alveolae. This group comprises the ciliates (Ciliophora Doflein 1901), the parasitic Apicomplexa including the malaria-parasite Plasmodium, and the Dinoflagellates.
- Several lineages within the Stramenopiles ($\rightarrow$ algae), which secondarily lost the plastid or reduced the plastid to a leucoplast. Important lineages are, for instance, the Bicosoecida and the chrysomonads (= chrysophytes). These lineages are closely related to major algal groups such as the (see entry *Diatoms*) (Bacillariophyceae) and the brown algae (Phaeophyceae).
- Cryptophyceae Pascher 1913 (= Cryptomonads), again a group with pigmented phototrophic members and colorless phagotrophic members.

Ecology, microbial food web, and functional groups

In aquatic environments, protist abundances usually range between 10^2 mL^{-1} and 10^4 mL^{-1} . The dominant taxonomic groups among heterotrophic protist communities within different marine, brackish, and limnetic pelagic communities (heterokont taxa, dinoflagellates, choanoflagellates, katablepharids, and ciliates) and benthic communities (euglenids, bodonids, thaumatomonads, apusomonads, cercoconads, and ciliates) are relatively similar. Soil samples contain between 10^4 and 10^8 active protist individuals per gram soil and litter, with flagellates being the most dominant group followed by gymnamoebae, testate amoebae, and ciliates. Numbers decrease with increasing soil depth and are usually lower in unplanted soil. Bacterivorous protists are the most important among secondary saprotrophs; the main bacterivores belong to the bodonids and the cercoconads,

which comprise most soil flagellates, the colorless chrysomonad *Oikomonas*, the Vahlkampfiidae, the gymnamoebae, Testacealobosia, and dictyostelids (Amoebozoa), the filose testate amoebae, and the ciliates. Soil protists may be responsible for up to 70% of the soil animal respiration and for 14–66% and 20–40% of the mineralization of C and N, respectively.

In protozoan feeding, either phagotrophy or osmotrophy predominate in particular species. In addition, chlorophyll-bearing flagellates profit from photosynthesis. Some Protozoa, specifically small flagellata and some filter-feeding ciliates are among the most important consumers of bacteria whereas many of the larger Protozoa prefer algae and smaller Protozoa as food. Life observations on food uptake provided early insights in these functional differences. The more recent research foci on the plant–animal–fungi–protist distinction and the bacterial ingestion as basic in the serial endosymbiosis theory further extended this research direction. This line of thinking based on functional groups culminated in the 1980s in the formulation of the microbial loop concept with heterotrophic phagotrophic flagellates and ciliates as

consumers of bacteria (Figure 1). In general, phagotrophic protists ($\approx$ Protozoa) are a major component in any ecosystem and are responsible for the majority of eukaryotic respiration and production whereas their autotrophic counterparts are important primary producers. Protists are key mediators in the enhancement of nutrient flow by regulating decomposition rates and specific metabolic pathways to the benefit of plants and microorganisms in soil and aquatic habitats. Bacterial production is stimulated by protists excreting secondary metabolites, excess nitrogen, and phosphorous in the form of ammonium, inorganic phosphorous, or organic compounds. They channel carbon and nutrient flow from one of the largest standing stocks of living biomass, that is, bacteria (see entry *Bacteria*) and archaea (see entry *Archaea*), to higher trophic levels. Thus, with respect to global biogeochemical cycles (see entry *Biogeochemical Cycles*), phagotrophic protists are a major force that shape the movement and fate of microbial biomass in any ecosystem. Selective grazing has already been demonstrated with respect to prey size, cell wall chemistry, nutritional value, activity, and the ability to produce inhibitory compounds.

Protozoa (Heterotroph, Eukaryotic), Figure 1 The microbial food web. A substantial portion of the primary production is channeled through the microbial food web. Dissolved organic carbon is utilized by bacteria, which are grazed by protozoa.

Fossil record

Protozoa are important in reconstructing past ecological conditions as several protozoan taxa form microfossils. The fossil remains of Protozoa are naturally confined to

those classes or orders, which are shell-producing during life. They are most common in deposits of marine environments, but also occur in brackish water, fresh water, and terrestrial sedimentary deposits.

Protozoa (Heterotroph, Eukaryotic), Figure 2 (a–c) Cercozoa are abundant protozoa in soils and sediments. (a) *Cercomonas braziliensis*; (b) *Paracercomonas* sp. (c) *Filoreta marina*; (d–g) Unpigmented chrysomonad flagellates have been regarded as protozoa but are now placed within the Chromista. (d, e) Chrysomonad (=chrysophycean) resting stages (stomatocysts); (f) Surface scales of chrysophytes; (g) Resting stage covered in surface scales. Figures 2a, b and c are courtesy of David Bass, The Natural History Museum, London, UK.

Radiolaria (see entry [Radiolaria](#)) build mostly tests from opal (hydrated silica), some from silica and organic material, and some from strontium sulphate. They are important index fossils and a source of marine silica cements, chert (see entry [Cherts](#)), etc. Foraminiferans (see entry [Foraminifera](#)) have typically multichambered tests, although some are unilocular. Foraminiferans are important as biostratigraphic index fossils and as a reliable source of untransported carbonate shell material for stable-isotope analyses. Further, the Paleozoic Acritarchs (nonacid soluble organic structures, potentially cysts) and Chitinozoa (chitinous organic-walled flask-like chambers) potentially are also protozoan microfossils. Besides the fossils of heterotrophic taxa, specifically several Chromist taxa ([diatoms](#), golden algae) build important microfossils such as the diatoms (see entry [Diatoms](#)), the Coccolithophorids (see entry [Chroococcidiopsis](#)), and the golden algae ([Figure 2](#)).

Diversity and biogeography: “everything is everywhere”?

Two main hypotheses about the causes of nonrandom distribution of microorganisms continue to obtain conflicting experimental support: the idea that “everything is everywhere” is based on the assumption that the enormous dispersal capabilities of microorganisms allow them to spread into virtually any habitat. Absence of taxa is caused by unfavorable local conditions that prevent them from getting established everywhere. In a contrasting model, the rate of dispersal of microorganisms is not sufficiently high to overcome historical dispersal limitations and human influence. This allows for existence of endemic taxa many of which remain to be discovered. Adjusting the species concepts is a necessary precondition for drawing conclusions about derived theories such as flagellate biogeography and the “everything is everywhere” debate. The predominant view of a low to moderate number of nanoflagellate taxa, most of which seem to be globally distributed and ubiquitous, is increasingly replaced by the view of a tremendous number of taxa with a much more restricted distribution, both with respect to habitat type and geographic distance.

Summary

Protozoa are a loose grouping of organisms with usually unicellular organization and heterotrophic mode of nutrition. The systematic position of the Protozoa and related organisms remained and still remains unclear for many lineages. Functional groups based on rough morphological characters comprise amoeboid, flagellated, and ciliated organisms. Protozoa are a major component in any ecosystem and are responsible for the majority of eukaryotic respiration and production whereas their autotrophic counterparts are important primary producers. Protists are key mediators in the enhancement of nutrient flow by regulating decomposition rates and specific metabolic pathways to the benefit of plants and microorganisms in

soil and aquatic habitats. They build important microfossils both in the marine and in freshwaters.

R

RADIOACTIVITY (NATURAL)

Beda A. Hofmann
Natural History Museum Bern, Bern, Switzerland

Synonyms

Natural radiation; Terrestrial radiation

Definition

Natural radioactivity (NR) is predominantly due to the decay of ^{238}U , ^{235}U , ^{232}Th (and their chains of daughter elements), ^{87}Rb (27.8% of natural Rb), and ^{40}K (0.012% of natural K). Early in the Earth's history ^{244}Pu (half life 82.6 Ma) also was an important radioelement. These are all primordial isotopes formed prior to the origin of the solar system. The list of natural radioisotopes also includes primordial ^{147}Sm and ^{187}Re and short-lived cosmogenic isotopes such as ^{10}Be , ^{14}C , and ^{26}Al . Of all these elements, only U, Th (including daughter elements) Rb, and K represent significant sources of terrestrial natural radioactivity. U, Th, and daughters are emitters of alpha and beta particles and gamma rays; ^{87}Rb emits beta particles, ^{40}K is a beta and gamma emitter. Another source of NR are the cosmic rays, dominantly protons (and minor He nuclei) with a very wide range of energies. The higher energetic ones are of galactic origin, while the sun contributes on the lower energy side of the spectrum. Upon arrival in the atmosphere, a cascade of secondary particles is created (air shower) which ultimately may affect life on the surface. The Earth's surface is heavily shielded from cosmic rays by both its magnetic field and its atmosphere (Bauer and Lammer, 2004). The contribution of cosmic rays to the natural dose of radioactivity is strongly dependent on altitude and ranges from a minor fraction at sea level to dominant at high altitudes.

The radioactive elements U, Th, Rb, and K are strongly concentrated in the continental crust, and a large part of these elements are relatively evenly distributed with an average concentrations in crustal rocks of 2.7 ppm U, 9.6 ppm Th, 90 ppm Rb, and 2.1% K (2.5 ppm ^{40}K). The specific activities, including all daughter elements in secular equilibrium, are 179 Bq/kg for 1 ppm U, 41 Bq/kg for 1 ppm Th, 0.87 Bq/kg for 1 ppm Rb, and 302 Bq/kg for 1% K. Natural enrichment processes can lead to local concentrations much higher than the crustal average. High-grade ores may contain several percent U or Th and up to 52% K (sylvite). The most radioactive mineral is uraninite UO_2 with up to 88% uranium and a specific activity of $1.58 \cdot 10^8$ Bq/kg (Figures 1 and 2). Natural chemical or physical separations between U, Th, and their daughter elements can lead to U enrichments lacking daughters (until equilibrium is reached again) or enrichments of daughters unsupported by parent elements. Such disequilibria are of geologically short duration (few half lives) and do occur at sites of high element turnover, e.g., in submarine hot springs (Jolivet et al., 2003) and in the oxidation zone of uranium ores. Radioactive hot spots may form due to accumulation of short-lived daughter elements, e.g., ^{210}Po and ^{210}Pb in hydrothermal vents, and locally cause high doses to fauna (Cherry et al., 1992).

The separation of the short-lived ^{238}U daughter ^{222}Rn , a noble gas, and its migration in groundwater and soil gas is of particular importance for human radiation protection.

A special case of NR are the 1.97 Ga natural fission reactors of the Franceville basin, Gabun (Mathieu et al., 2001). During the activity of these natural reactors, they must have been the sites with the highest NR on Earth ever.

The two related actinide elements uranium and thorium show an important difference in chemical behaviour: Thorium only occurs in the tetravalent state Th(IV) and

Radioactivity (Natural), Figure 1 Uraninite as an accessory mineral in granite (Böttstein well, northern Switzerland). Around the crystal of the radioactive mineral a halo is visible corresponding to the range of alpha particles (approx. 20 μm) that destroyed (amorphized, metamictized) the crystal lattice of the enclosing K-feldspar within their range. Scattered red hematite particles are indicative of oxidizing conditions due to water radiolysis. The age of this uraninite is approximately 330 Ma. Reflected light, maximum diameter of crystal is 50 μm .

Radioactivity (Natural), Figure 2 Detrital uraninites from the Witwatersrand gold fields, South Africa (Blijvooruitzicht Mine). Uraninite is sprinkled with galena originating from radioactive decay of uranium, and mantled by kerogen-type organic matter (brownish without galena inclusions) due to the immobilization of mobile hydrocarbons as a result of irradiation. The age of these uraninites is in the order of 3000 Ma. Bright yellow mineral is pyrite. Reflected light, field of view is 220 μm .

is nearly immobile (very low solubility) under ambient conditions. Uranium occurs in two major states of oxidation: U(IV) is immobile as thorium, but U(VI), mainly occurring in the form of the uranyl ion UO_2^{2+} , is very soluble and the stable form in chemical equilibrium with the Earth's oxidizing modern atmosphere (Figure 3). Uranium accumulations due to reducing barriers and microbial redox interactions can therefore be expected in the case

Radioactivity (Natural), Figure 3 Precipitations of an amorphous uranium-(VI)-Al-silicate phase from water seeping out of fractures and a borehole on a granite tunnel wall. Krunkelbach uranium mine (240 m level), Menzenschwand, Germany, September 1987. This image demonstrates the high mobility of uranium in oxidized near-surface waters. Field of view 1 m.

of uranium, but not for thorium. Uranium thus plays a special role among natural radioactive materials because its minerals have the highest specific activity, and can be formed as a result of low-T redox processes.

There are a range of different interactions, certain and potential, between NR and life on Earth, and, potentially, on other celestial bodies. Such interactions may be direct (affecting organisms) or indirect (changes of the environment or of products of life). The most important interactions between life and NR are summarized here:

- (a) NR is a potentially detrimental factor for life, causing gene damage and, at high doses, cell death. The doses of NR are only relevant for gene damage with rare exceptions (Oklo reactors during their activity). For dormant microbial spores unable to perform repair processes, the situation may be drastically different and NR may pose a limiting factor for the long-term survival. NR in the form of cosmic rays is a limiting factor during the actual (manned space missions) and potential presence of life in space, e.g., dormant spores inside a meteoroid being transferred from one planetary body to another in a process called lithopanspermia (Mileikowski et al., 2000).
- (b) The low doses of NR on the Earth's surface are important for evolution in producing a range of mutations as a basis for natural selection.
- (c) Microbial life has found ways to adapt to high doses of NR by applying highly efficient DNA repair mechanisms. Such organisms include the bacteria *Deinococcus radiodurans* and *Thermococcus gammatolerans* (Jolivet et al., 2003). Apparently in *D. radiodurans* this mechanism, unlikely to evolve in environments of low NR, was developed as a

means to deal with desiccation (Mattimore and Battista, 1996).

- (d) NR may have played a role in the origin of life through production of reactive organic and inorganic radicals (Parnell, 2004). Natural heavy mineral enrichments (placers) containing radioactive minerals may have been such sites at a time when the specific activity of radioactive minerals was significantly higher than today due to the presence of ^{244}Pu and higher levels of ^{235}U .
- (e) NR can cause the immobilization of biogenic hydrocarbons during migration. Polymerization of hydrocarbons leads to coatings of immobile organics on radioactive minerals (Rasmussen, 2005; Rasmussen et al., 1993). Such coatings are tracers of hydrocarbon migration, and of life in general (Figure 2). Organic matter in ore deposits generally shows signs of radiation-induced maturation (Hofmann, 2004).
- (f) In the near-surface environment of low-shielded planetary bodies (e.g., Mars), destruction of biomolecules (e.g., amino acids) as a result of radiolytic destruction due to cosmic ray bombardment is potentially important over geological time scales (Kminek and Bada, 2006). This puts limits on the detectability of molecular biosignatures.
- (g) In certain deep subsurface environments, NR is a key source of chemical energy for microbial life. Through radiolysis of water, kinetically inert reductants (H_2) and oxidants (H_2O_2 as short-term product, sulfate as possible long-term product) may be formed. These and related compounds may then serve as an energy source for microbial growth (Hofmann, 1992; Jørgensen and D'Hondt, 2006; Lin et al., 2005; Lin et al., 2006; Savary and Pagel, 1997).
- (h) Generation of local anomalies of NR through direct or indirect microbial reduction of uranium. Both direct enzymatic reduction (Lovley et al., 1991, 1993) and indirect reduction due to microbial production of hydrogen sulphide (Mohagheghi et al., 1985) may be relevant. Microbial cells may become mineralized by uranium phases (Milodowski et al., 1990).
- (i) NR is the most important source of geothermal heat and thus a major driver of plate tectonics. This makes NR one of the key influences on geological processes, with which life on Earth is intimately interwoven.

Conclusions

Life on Earth would be different and maybe even nonexistent without natural radioactivity, and the environment would be a totally different one. Natural radioactivity plays only a minor role in the life of single individuals or generations of the bulk of microbial and higher life on Earth, but is a key factor in evolution. In specific extreme environments, like the deep subterranean biosphere, natural radioactivity may provide a crucial energy source.

RADIOLARIA

Volker Thiel
University of Göttingen, Göttingen, Germany

Radiolaria are planktonic marine protozoa showing unicellular organization and heterotrophic mode of nutrition. They build tests varying in shape from simple scattered spicules to highly ornated geometric-shaped shells (Adl et al., 2005). Sizes usually range from hundredths to tenths of millimeters. The tests are made from opal (hydrated silica), some from silica and organic material, and some from strontium sulphate. The name “Radiolaria” derives from the marked radial skeletal spines that characterize many species. Radiolarians are known from the very beginning of the Paleozoic (early Cambrian of the Yangtze Platform; Braun et al., 2007). They are important index fossils and may significantly contribute to marine silica-rich sediments. Radiolarian cherts (radiolarites), a variety of chert (see entry *Cherts*) composed of radiolarian remains, indicate deep water deposition at depths below which siliceous sediments are stable, but carbonates are dissolved. See entry “*Protozoa (Heterotroph, Eukaryotic)*” for further reading.

Definition

Confocal Raman microscopy (CRM) is a nondestructive analytical technique that merges Raman spectroscopy and confocal microscopy for the visualization of molecular information over a defined sample area.

Introduction

Raman spectroscopy is well suited for studies in mineralogy and petrography, as it provides nondestructive mineral identification fast and with high specificity. In addition, Raman spectroscopy allows the characterization of complex organic materials, which makes it particularly useful in biogeoscience applications (Hild et al., 2008). This technique has long been applied in geosciences, for example, for the identification and characterization of minerals, or in the observation of mineral phase transitions in high and ultra-high pressure/temperature experiments. In most cases, measurements have been carried out in a micro-Raman set up, i.e., information was obtained from single or multiple points of interest on a sample. This way, little detail on the spatial distribution and association of components or mineral phases, or chemical variation could be observed, even though this information may contribute significantly to the understanding of a sample's complexity.

By means of CRM, such sample characteristics can be evaluated from large scale scans in the centimeter range to the finest detail with sub-micron resolution. Modern confocal Raman microscopes allow for such measurements with very high sensitivity and spatial as well as spectral resolution. CRM is a tool that not only provides complementary information to data obtained by e.g., electron microprobe (EMP), energy dispersive x-ray analysis (EDX), or secondary ion mass spectrometry (SIMS). In addition to the quantitative and semiquantitative elemental and/or isotopic data acquired by these techniques, CRM contributes the visualization of the distribution of molecular information over a defined sample area. Furthermore, considering that most geomaterials are transparent from the UV (NUV) to VIS and NIR to some degree, this information can be obtained three dimensionally due to the confocal set-up of the microscopes. The following discussion provides background information and examples that shall serve to highlight some key analytical features of this technique for applications in geosciences. A recent and comprehensive summary on the application of CRM in Geoscience can be found in Fries and Steele (2010).

Definition

Confocal Raman microscopy (CRM) is a nondestructive analytical technique that merges Raman spectroscopy and confocal microscopy for the visualization of molecular information over a defined sample area.

Introduction

Raman spectroscopy is well suited for studies in mineralogy and petrography, as it provides nondestructive mineral identification fast and with high specificity. In addition, Raman spectroscopy allows the characterization of complex organic materials, which makes it particularly useful in biogeoscience applications (Hild et al., 2008). This technique has long been applied in geosciences, for example, for the identification and characterization of minerals, or in the observation of mineral phase transitions in high and ultra-high pressure/temperature experiments. In most cases, measurements have been carried out in a micro-Raman set up, i.e., information was obtained from single or multiple points of interest on a sample. This way, little detail on the spatial distribution and association of components or mineral phases, or chemical variation could be observed, even though this information may contribute significantly to the understanding of a sample's complexity.

By means of CRM, such sample characteristics can be evaluated from large scale scans in the centimeter range to the finest detail with sub-micron resolution. Modern confocal Raman microscopes allow for such measurements with very high sensitivity and spatial as well as spectral resolution. CRM is a tool that not only provides complementary information to data obtained by e.g., electron microprobe (EMP), energy dispersive x-ray analysis (EDX), or secondary ion mass spectrometry (SIMS). In addition to the quantitative and semiquantitative elemental and/or isotopic data acquired by these techniques, CRM contributes the visualization of the distribution of molecular information over a defined sample area. Furthermore, considering that most geomaterials are transparent from the UV (NUV) to VIS and NIR to some degree, this information can be obtained three dimensionally due to the confocal set-up of the microscopes. The following discussion provides background information and examples that shall serve to highlight some key analytical features of this technique for applications in geosciences. A recent and comprehensive summary on the application of CRM in Geoscience can be found in Fries and Steele (2010).

Principles of confocal Raman microscopy

CRM essentially merges two techniques into one. First, Raman spectroscopy, which allows nondestructive chemical analysis; secondly, Confocal microscopy which allows the user to examine samples with diffraction-limited resolution as well as to obtain three-dimensional information from the sample. The theory behind these two techniques will be explained in the following sections, followed by an illustration of how images with chemical sensitivity can be obtained using this combination of techniques.

Raman spectroscopy

When light of a certain wavelength interacts with a molecule, most photons are elastically scattered and therefore have the same energy as the incident photons. However, a very small fraction (approximately 1 in 10^6 – 10^7 photons) is inelastically scattered, which means that the energy of the scattered photon is different than the energy of the incident photon.

This is called the “Raman effect”, and it was discovered by Sir Chandrasekhara Raman in 1928 (Raman, 1928; Raman and Krishnan, 1928). Unlike today, he used a filtered beam of sunlight as an excitation source and his eye as a detector for the frequency shifted light. This was long before the development of the first laser by Maiman in 1960. Raman was awarded the Nobel Prize in 1930 for this discovery. The theory behind the Raman effect was derived five years earlier by Smekal (1923).

The tremendous importance of the Raman effect lies in the fact that the energy shift between the exciting and the Raman scattered photon is caused by the excitation (or annihilation) of a molecular vibration. This energy shift is thus characteristic and therefore a fingerprint for the type and coordination of the molecules involved in the scattering process.

Theory

The following section shall provide some basic descriptions and definitions relevant to Raman spectroscopy. Readers interested in a detailed theoretical background are referred to Ibach and Lüth (2003).

In quantum mechanics, the scattering process between a photon and a molecule is described as an excitation of a molecule to a virtual state lower in energy than a real electronic state and the (nearly immediate) de-excitation. The lifetime of the virtual state is extremely short and can be calculated by the Heisenberg uncertainty relation:

$$\Delta t \cdot \Delta E \geq \frac{\hbar}{2} \quad (1)$$

With typical photon energies of 1–2 eV, the lifetime of the excited state is only about 10^{-15} s. After this extremely short time, the molecule falls back either to the vibrational ground state or to an excited state (Figure 1). When the initial and final states are identical, the process is called Rayleigh scattering.

If the initial state is the ground and the final state a higher vibrational level, the process is called Stokes scattering, if the initial state is energetically higher than the final state, this is referred to as Anti-Stokes scattering. The difference in energy between the incident and the Raman scattered photon is equal to the energy of a vibration quantum of the scattering molecule. A plot of intensity of scattered light versus energy difference is called a Raman spectrum.

The position of a Raman line is usually given in relative wavenumbers ($1/\text{cm}$), which is the energy shift relative to the excitation line:

$$\bar{\nu} = \frac{1}{\lambda_{\text{incident}}} - \frac{1}{\lambda_{\text{scattered}}} \quad (2)$$

Raman Microscopy (Confocal), Figure 1 Energy level diagram for Raman scattering.

Raman Microscopy (Confocal), Figure 2 Typical Raman Spectrum.

$\lambda_{\text{incident}}$ and $\lambda_{\text{scattered}}$ are the wavelengths of the incident and Raman scattered photons, respectively.

As can be seen in Figure 2, a typical Raman spectrum is symmetric to the Rayleigh line and the Anti-Stokes lines are lower in intensity than the Stokes shifted lines.

From classical scattering theory, one finds that the intensity I of scattered light is proportional to the 4th power of the excitation frequency

$$I \propto \nu^4 \quad (3)$$

Exciting a sample with blue light at 400 nm would therefore give a 16 times higher Raman signal than using red light at 800 nm. The problem of using blue (or UV) excitation light, however, is fluorescence. Many samples show fluorescence when they are excited with blue light and Raman emissions are extremely weak compared to fluorescence. If a sample shows significant fluorescence, obtaining a Raman spectrum is usually impossible because the fluorescence background covers the Raman signal. In the red (or even IR) region of the spectrum, fluorescence is usually not a problem, but the excitation intensity must be much higher ($I \propto \nu^4$). Another problem is that Silicon detectors cannot be used above 1100 nm (band gap energy of Si: 1.12 eV). Other IR detectors (such as InGaAs) show much more thermal and readout noise than silicon and photon counting detectors with low dark count rates are not available yet. In real experiments one must always find a compromise between detection efficiency and excitation power.

Confocal microscopy

Confocal microscopy allows the user to obtain three-dimensional information from the sample. It requires a point source (usually a laser), which is focused onto the sample. The reflected light (Rayleigh, Raman, fluorescence) is collected with the same objective and focused through a pinhole at the front of the detector (Figure 3). This ensures that only light from the image focal plane

Raman Microscopy (Confocal), Figure 3 Principal setup of a confocal microscope.

can reach the detector, which greatly increases image contrast and with the proper selection of pinhole size, slightly increases resolution (max. gain in resolution: factor $\sqrt{2}$). As can be seen from Figure 3, light originating from planes other than the focal plane will be out of focus at the pinhole. Therefore, its contribution to the detected signal is strongly reduced. Additionally, by changing the distance between the objective and the sample, the focal plane is moved within the sample thus allowing depth profiling or even 3D imaging (Wilson, 1990).

Pinhole size

The choice of the pinhole size is important because on one hand the signal should be as high as possible, while on the other hand the image should be as confocal as possible (highest depth resolution). To take full advantage of the lateral and depth resolution possible with confocal microscopy, the size of the pinhole should be adjusted and optimized. To obtain the highest lateral resolution, the pinhole size should be below $\nu_p = 0.5$. (The variable ν describes the position in optical coordinates and can be derived from $\nu = \frac{2\pi}{\lambda} \sqrt{x^2 + y^2} \sin \alpha$. Here λ is the excitation wavelength, x and y the sample coordinates in the focal plane and α half of the aperture angle. ν_p is the radius of the pinhole in optical coordinates when assuming a magnification of 1.) However, at this point the transmission through the pinhole is only 5% of the scattered intensity. In practice, the pinhole size can be up to $\nu_p = 4$ without significantly changing depth resolution and up to $\nu_p = 2$ without significantly changing lateral resolution. It can be shown that if $\nu_p > 4$, the

resolution of at least a conventional microscope remains. This is due to the fact that for a large detector the resolution is always determined by the diameter of the excitation laser spot. Only the depth resolution (and therefore contrast for a thick sample) is lost in this case. In most cases, a pinhole size of $v_p = 2.5$ is a good compromise since good depth resolution is maintained while $>75\%$ of the light still reaches the detector (see Figure 4).

For the experiment, the relation

$$\frac{M}{NA} \geq \frac{\pi d_0}{v_p \lambda} \quad (4)$$

should be fulfilled, where M is the magnification, d_0 the diameter of the pinhole, and NA the numerical aperture of the objective. The left side of this equation is defined by the objective and the beam path and the right side by the wavelength, the pinhole size itself and v_p . If, for example, an objective with a magnification of $100\times$ and a numerical aperture of 0.9 is used at a wavelength of 532 nm the optimum pinhole size would be 50 μm for maximum depth resolution and 10 μm for maximum lateral resolution.

In actual experiments, one usually has to find a compromise between the highest resolution and collection efficiency. This is very important in CRM because Raman is an extremely weak effect. If a very small pinhole is used, the collection efficiency is strongly reduced (Figure 4).

This graphic shows the intensity on the detector as a function of pinhole size, normalized to the total intensity in the image plane. One can see that the collection efficiency is about 75% for maximum depth resolution ($v_p = 2.5$), but only 6% for maximum lateral resolution ($v_p = 0.5$).

Using the appropriate pinhole size, it is therefore always possible to obtain maximum depth resolution.

Raman Microscopy (Confocal), Figure 4 Collection efficiency as a function of the pinhole size normalized to the total power in the image plane.

Resolution

For sample scanning systems, the magnification printed on the objective used is of minor importance. The maximum scan range achievable by the sample scanner determines the maximum image size, independent of the magnification of the objective. The more important property of the objective is the numerical aperture, which together with the excitation wavelength determines the lateral resolution of the objective. The magnification is only important for the choice of the pinhole size.

The maximum resolution of a classical microscope is given by the Rayleigh criterion

$$\Delta x = \frac{0.61 \lambda}{NA} \quad (5)$$

where Δx is the smallest distance between two point objects that will appear separated in the image plane, λ is the wavelength of the excitation light, and NA is the numerical aperture of the microscope objective. In this case, the image of two point objects will appear just separated (Figure 5).

Confocal Raman microscopy

Instrumentation considerations

When combining confocal microscopy and Raman spectroscopy the main challenge is the low signal intensity. As mentioned earlier, only one in about $10^6 - 10^7$ photons is frequency shifted by the Raman effect. Thus the number of photons reaching the detector is far less than is the case for confocal or fluorescence microscopy. The two obvious

Raman Microscopy (Confocal), Figure 5 The intensity distribution of two point sources which are separated by the Rayleigh criterion.

changes would be to increase the laser power and to increase the integration time. However, there are limitations to these possibilities as shown below:

- (a) *Laser power*: If a power of only 1 mW from a 532 nm laser is focused diffraction limited using a $100\times$ air objective with a NA of 0.9, the power density in the illuminated spot is approximately 10^6 W/cm². These levels are only possible because a single point is illuminated and the heat effectively dissipates in three dimensions. Nevertheless, the maximum laser power on the sample is therefore typically in the range of 1–20 mW.
- (b) *Integration time*: Increasing the integration time will increase the signal to noise ratio significantly. However, when CRM or mapping is applied, in which an image is produced by recording a spectrum at every image pixel, the integration time per spectrum needs to be kept to a minimum. An integration time of only 1 s per spectrum will, when recording an image of 128×128 pixels, result in a total acquisition time of about 4.5 h, which is an inconvenient time-span for routine application.

Therefore, a system for CRM must be capable of obtaining the Raman spectra with an acceptable signal-to-noise ratio in less than 50–100 ms. There are several parts of a confocal Raman microscope which should be optimized in order to allow such rapid data acquisition. These will be discussed in the following:

Laser power: As described above, the maximum laser power is limited and will heavily depend on the destruction and alteration threshold of the sample used.

Collection efficiency of the objective: Using objectives with high numerical apertures maximizes the collection efficiency since light from a larger solid angle is collected.

Throughput of the microscope: In order to enhance the throughput of the microscope, the components used within the beam path should be optimized and if possible minimized since every passive optical element introduces losses to the signal.

Efficiency of the grating: Highly efficient gratings with the correct blazing angle for the excitation wavelength should be used. As an example: a grating blazed at 500 nm will have an absolute efficiency of >60% up to 3000 rel.1/cm when using a 532 nm laser. Using the same grating with a 785 nm laser will cause the efficiency to drop to about 30% at 3000 rel.1/cm. The correct grating blazed at 750 nm, however, shows an efficiency >60% up to 3000 rel.1/cm when used with the 785 nm laser.

Efficiency of the spectrometer: There are a variety of spectrometers available on the market. While mirror-based spectrometers can generally be used over a wide spectral range, lens-based spectrometers often show a higher throughput in the spectral range they are designed for. Some lens-based spectrometers show a transmission at 532 nm of >60%. Spectrometers using a combination of lenses and prisms or mirrors generally have a significantly lower throughput. Commercially available mirror-based

Czerny-Turner spectrometers only have a transmission of about 30% at this wavelength.

Efficiency of the detector (CCD): Back-illuminated CCD cameras show a quantum efficiency (QE) of >90% over the entire spectral range of interest for 532 nm excitation. Deep depletion back-illuminated CCD cameras, on the other hand, show a QE of >90% for 785 nm excitation. As a comparison, front-illuminated CCD cameras do not exceed 55% quantum efficiency at any wavelength.

Additionally, the dark current of the cameras needs to be minimized, which is achieved through efficient Peltier cooling.

The readout noise is another limiting factor for small signals. As the analog to digital (A/D) converter of all cameras will add at least 5–10 electrons read-out noise to the signal, any signal below approximately 5 electrons will be lost in the noise. Additionally, the faster the A/D converter is operating, the higher the read-out noise will be. Electron-multiplying CCD (EM-CCD) cameras can be used to overcome this problem. With these cameras, the signal is amplified before the A/D conversion, allowing the detection of even single photons and reducing the necessary integration time down to milliseconds.

Principle of operation

Confocal Raman microscopes generally provide a variety of modes of operations. The most common are listed below:

Collection of Raman spectra at selected sample areas (single spectrum): Single Raman spectra can be collected at user-selectable sample areas with integration times ranging from ms to hours. The position of the collected spectrum can normally be fully controlled in 3D. A stable and precise positioning system must be included in the instrument to ensure that the point of interest will remain fixed under the excitation focus. This is very important when spectra with longer integration times for the best quality and signal to noise ratio are to be obtained from extremely small sample volumes. For example, using an oil immersion objective (NA 1.4) with a 532 nm laser and the proper pinhole size allows the sample volume to be as small as $\approx 230 \times 230 \times 550$ nm.

Collection of time series of Raman spectra at selected sample areas (time spectrum): With this mode, time series of Raman spectra can be obtained to analyze dynamic sample properties. Thousands of spectra can be obtained over time and analyzed with integration times ranging from ms to tens of seconds.

Raman spectral imaging: In the Raman spectral imaging mode, the sample is moved in X and Y and a full Raman spectrum is obtained at every pixel measured. From these data sets images of, e.g., the integrated intensity of various bands can be generated. This is illustrated in the following example.

A drill core section from the Äspö Hard Rock Laboratory, Sweden, was studied using the large area scan mode CRM, aiming to characterize secondary fracture fillings in

a 1.8–1.4 billion years old diorite. The rock sample was obtained from ~450 m below the surface (kindly provided by SKB, Swedish nuclear fuel and waste management). This sample was examined with a 532 nm laser and a 50× air objective (NA 0.55). The scan range was 8000 μm in X and 2000 μm in Y with 800×200 points resolution. Each spectrum was integrated for 36 ms. Figure 6 shows the characteristic spectra of calcite, fluorite and quartz found in the sample. Integrating over, for example, the area marked in green in Figure 6d results in a single value for each of the 160,000 spectra. These spectra can be displayed as a color-coded image as shown in Figure 6a for quartz. Here, brighter values indicate a higher integrated intensity of the quartz peak and the distribution of quartz can thus be obtained from this image.

Other spectra of the same scan show the characteristic features of calcite or fluorite (Figure 6d). Using these, the calcite (Figure 6b) and fluorite (Figure 6c) images can be generated by using additional integral filters for the marked regions. Other features of the spectra such as the width of peaks or their position can also be evaluated by applying the corresponding filters.

Further evaluation of the data allows the averaging of similar spectra (for which a cluster analysis is often used) and the subtraction of, for example, pure spectra from mixed spectra to extract the spectra of the various components (spectral de-mixing). These spectra can then be used with the basis analysis, where each of the spectra recorded are fitted with a linear combination of the basis spectra. The result of such an analysis is one image for each basis

Raman Microscopy (Confocal), Figure 6 Spectra (d) and spectral images of quartz (a), calcite (b) and fluorite (c) recorded from the diorite (a) and the fracture fillings (b and c). The data were recorded with a WITec alpha500R confocal Raman microscope.

Raman Microscopy (Confocal), Figure 7 DE-mixed and averaged spectra of the various components in the diorite and the adjacent fracture minerals with the combined image on the left.

Raman Microscopy (Confocal), Figure 8 Variations in the quartz phases due to changes in the crystallographic orientation, the crystallinity, and the minerals.

spectra which can then be combined to generate a false color image showing the distribution of all components (Figure 7).

The color-coded Raman image and corresponding spectra in Figure 7 allow for the general assignment of mineral phases and their gross distribution over the scanned area. In addition to the mineralogical context information, organic components were identified, spectrally characterized and located, trapped between two generations of fracture fillings (the hydrothermal fluorite and low temperature calcite, Tullborg et al., 2008; Wallin and Petermann, 1999). This information allowed to infer at which point in time a “deep biosphere” (see entry “*Terrestrial Deep Biosphere*”) was active within these rocks.

Cluster analysis of the data set revealed discrete areas of variation in the mineral phases (Figure 8). This is exemplified by the quartz phase where four distinct regions were identified based on variations in relative peak intensity. Plotting regions of equal intensities of the quartz line at ca. 200 cm^{-1} shows discrete regions in the sample corresponding to each of the identified spectra.

Quartz was selected as an example to highlight the feasibility of color-coded Raman imaging to locate changes of different mineral phases. These changes can likely be attributed to different levels of crystallinity and crystal orientation. It is noteworthy that the discrete phase colored green only occurs at the interface with the plagioclase minerals, which can be attributed to a secondary phase due to the alteration and phase changes of the plagioclases. Since SiO_2 -phases play an important role in biomineralization, this example highlights the potential benefits confocal Raman imaging may provide in understanding the processes and dynamics involved in these processes.

Summary

CRM is a nondestructive analytical technique that merges Raman spectroscopy and confocal microscopy for the visualization of molecular information over a defined sample area. The technique makes use of the Raman effect (Raman, 1928), i.e., the energy shift between exciting and scattered photons which is caused by the excitation (or annihilation) of a molecular vibration. This energy shift is characteristic and therefore a fingerprint for the type and coordination of the molecules involved. By means of CRM, the spatial distribution and association of components in the sample, including organics as well as minerals, can be evaluated from large scale scans in the centimeter range to the finest detail with submicron resolution. This way, CRM may contribute significantly to the understanding of a sample’s chemical composition, and complexity, in geological and geobiological studies.

REDUCTION SPHEROIDS

Beda A. Hofmann
 Natural History Museum Bern, Bern, Switzerland

Synonyms

Bleaching haloes; Fish eyes; Radioactive concretions; Radioactive nodules; Reduction mottling; Reduction spots; Reduktionshöfe

Definition

Reduction spheroids are small-scale (diameter: few millimeters to maximum about 20 cm) spheroidal bleached features in red-bed sediments characterized by the absence of hematite and often containing a mineralized core (center, [Figure 1](#)). Reduction spheroids result from local chemical reduction of ferric iron and other elements. Host rocks are marine and continental red beds and, more rarely, altered, hematite-stained crystalline rocks. Reduction spheroids have been described from many occurrences in red beds of widely variable age worldwide: Proterozoic of Canada (Tanton, 1948); Cambro-Silurian marine red beds of the NE USA (Beutner and Charles, 1985); Devonian continental red beds of Scotland (Parnell, 1985); Carboniferous continental red beds of New Brunswick and Nova Scotia, Canada (Dyck and McCorkell, 1983); Permian continental red beds of Germany (Eichhoff and Reineck, 1952; Mempel, 1960; Schreiter, 1930), Switzerland (Hofmann, 1990, 1991), Southwest England (Harrison, 1970; Perutz, 1940), and Cretaceous radiolarian cherts of Oman (Hofmann, 1991). Reduction spheroids characteristically consist of a spheroidal volume of rock from which hematite pigment has been dissolved. Central dark cores often display pronounced concentric zonation. The cores are strongly enriched in numerous redox-sensitive elements (dominant V, but also U, Se, As, Ni, Co, Cu, Ag, Au, PGE, and others). The dominant mineral in reduction spheroid cores is the vanadium mica roscoelite $KV_2AlSi_3O_{10}(OH)_2$. Uraninite is another very common mineral, leading to an often increased radioactivity of reduction spheroids ([Figure 2](#)). Arsenides of Ni, Co, and Cu are also quite common. Radiometric dating of roscoelite, uraninite, and

Reduction Spheroids, Figure 1 Reduction spheroids in Triassic red bed (marly dolomite), Chinle Formation, Paradox Valley, Colorado, USA. These reduction spheroids are strongly enriched in V, Cr, and Au. Diameter of larger reduction spheroid is 8 cm.

Pb-depleted haloes indicates late diagenetic ages (Hofmann, 1990; Hofmann and Frei, 1996). Reduction spheroids often occur in large numbers in red beds and can constitute up to several vol% of the rock. Based on textural evidence, such as fracture-bound occurrences and mass-balance calculations (Hofmann, 1991), reduction spheroids cannot be due to detrital organic-rich particles. Instead, the formation must be due to locally catalyzed redox reactions between a mobile reductant and oxidants. The presence of isotopically light sulfides in some cores (Hofmann, 1991), indicating diagenetic sulfate reduction, as well as the need for a local catalyst, strongly favors a microbiological origin of reduction spheroids. Reductants may be mobile hydrocarbons or molecular hydrogen resulting from the radiolysis of pore water (Hofmann, 1992). The formation of reduction spots is most likely due to chemolithotrophic communities. Kerogen-like organic matter is occasionally present at some localities (Curiale et al., 1983; Parnell, 1985) but is lacking at many other occurrences (Hofmann, 1993).

Conclusion

Reduction spheroids are very common in red-bed sediments, and there are strong indications for an origin due to redox reactions between a mobile reductant and oxidized elements locally catalyzed by microbial activity. Reduction spheroids are thus easily visible features resulting from redox processes catalyzed by a deep biosphere of sediments, and represent a type of biosignature that may also be present in oxidized rocks on Mars. Reduction spheroids contain small-scale

Reduction Spheroids, Figure 2 α -Autoradiographs of uranium-enriched reduction spheroid cores, Weiherfeld well, Permian of northern Switzerland. REMINERALIZATION (OF ORGANIC MATTER)

Degradation of organic matter that results in net conversion of organic carbon to inorganic (oxidized) carbon species such as CO_2 or HCO_3^- . See entries "[Carbon \(Organic, Cycling\)](#)" and "[Carbon \(Organic, Degradation\)](#)" for further reading.

RHODOPHYTA

The Rhodophyta, also referred to as "red algae," are a distinct eukaryotic lineage of algae with simple plastids (two membranes, derived from primary endosymbiosis). Rhodophytes have a long geological record since the Mesoproterozoic (1.2 Ga). Today, they encompass about 670 largely marine genera with up to 4,500 species predominating the coastal and continental shelf areas of tropical, temperate, and cold-water regions. Red algae are significant as primary producers and providers of structural habitat for other marine organisms. Calcifying (coralline) red algae play an important role in the primary establishment and maintenance of limestone reefs. For further details, see entry "[Algae \(Eukaryotic\)](#)."

RNA-WORLD

The term "RNA-World," first suggested by Walter Gilbert in 1986, describes a popular concept on a hypothetical early stage in the origin of life on Earth. Based on discoveries of enzymatic activities in microbial ribonucleic acids (RNA), a system was suggested where primordial RNA molecules accounted for both, the storage of genetic information and catalytic functions necessary to assemble themselves in a primitive self-replicating system. The RNA molecules evolved in self-replicating patterns, using recombination and mutation to explore new functions and to adapt to new niches (Gilbert, 1986). Such a system would not have required the presence of DNA and/or protein enzymes for biochemical reactions. For further reading, please refer to "[Origin of Life](#)."

SALINITY HISTORY OF THE EARTH'S OCEAN

L. Paul Knauth
 Arizona State University, Tempe, AZ, USA

Definition

Salinity refers to the total quantity of dissolved salts in water and is normally about 35 parts per thousand (‰) in today's ocean. Due to problems with making accurate measurements of total salts, salinity is now normally

expressed as a ratio of the electrical conductivity of the seawater to that of a standard concentration of KCl solution. The concentration of the standard solution is set such that the ratio of the approximate average salinity of the ocean today is equal to 35. The previous concentration value (‰) is thus unnecessary, but it is still widely used to highlight the basic meaning of the term. The relative proportions of the dissolved constituents are approximately constant, so the amount of Cl^- , the major component, is a proxy for salinity. Salinity history refers to past changes in the amount of dissolved salts in sea water over geologic time.

Significance

Salinity is an important environmental variable affecting chemical balances and osmotic pressures in all living cells. It particularly affects metazoans, because the amount of dissolved oxygen available for respiration depends on oxygen solubility that decreases as salinity increases. Besides its direct effects on cellular biochemistry, salinity governs the temperature of maximum density of sea water and thus the global thermohaline circulation that influences ecosystems. Models of geochemical cycles yield no constraints on past salinity levels, and reliable geochemical proxies, isotopic records, or other possible indicators of ancient oceanic salinity are currently unknown. However, Na^+ and Cl^- constitute about 85% of the salt in the sea, so the geologic record of halite deposits allows insights into how ocean salinity may have varied with time.

Causes of salinity changes with time

Early ideas that steady riverine input of salt to the oceans causes salinity to increase with time failed to recognize the geologic processes that intermittently cause salt to be removed from the sea and then later released following tectonic uplift. Nor did they correctly assess the probable initial origin of salt in the sea or consider possible small changes in ocean volume over time. Salt in rivers is derived largely from groundwater dissolution of ancient marine salt beds deposited when sea water evaporated under arid conditions in low latitude, geographically restricted arms of the sea. Deposition of these “saline giants” depletes the ocean in salt and thus lowers salinity. Subsequently, these enormous deposits may be tectonically lifted above sea level. Depending upon elevation, descending groundwaters can eventually dissolve the deposit and debouch into streams or lodge as dense, saline brines deeper in the continental subsurface. In addition to the saline giants, carbonate depositional environments in shallow seas that flooded the continents in past times typically contained vast tidal flats and supratidal areas in which sea water intermittently evaporated. Partially evaporated sea water from these environments as well as their ephemeral salts dissolved by falling rains descended into the subsurface and lodged in sedimentary basins even where large saline giants were absent. Most large

sedimentary accumulations on continents thus have highly saline waters in the deep subsurface. The salts in these brines were also in sea water once and their sequestration on continents thus also served to lower salinity of sea water. The presence of salt beds and brines hundreds of millions of years old illustrates the enormous lengths of time salt extracted from the sea can remain isolated.

Salinity history for the past 540 Ma

Estimates of the salt inventory in sedimentary rocks have steadily grown as more and more subsurface deposits are discovered. The latest estimate by Hay et al. (2006) confirms that deposition of the saline giants is strikingly episodic (Figure 1). Over half of the salt currently identified was deposited between 100 and 300 million years ago following breakup of the supercontinent Pangea. Presumably, this breakup and subsequent drift of the continental fragments produced the unusual array of geographic, geologic, climatic, and ocean circulation conditions that Sonnenfeld (1984) argued were necessary to produce saline giants. It follows that ocean salinity should have declined during these times of exceptional withdrawal of salts from the sea. The amounts shown in Figure 1 are surely minimal estimates of the amount of salt withdrawn because some significant percentage has been dissolved by groundwaters to become brines in the strata beneath

the salt. Additionally, salt depositional basins are rimmed with clastic deposits adjacent to the surrounding highlands and these are conduits to the subsurface for the prodigious amounts of evaporite brine present when the salt was being deposited. Combined geochemical and isotopic studies have shown that deep basin brines are probably mixtures of partially evaporated sea water and brine created by fresh water dissolution of salt (Knauth, 1988).

Salinity should increase during periods when there are no giant salt extractions underway and when older, uplifted deposits are eroding into the sea. This is the current situation, so the old arguments that the oceans are increasing in salinity via riverine input of salt are understandable. There is no direct evidence yielding the amount of salt returned to the sea at any given past time. Instead, it is necessary to use models for continental sediment erosion that are based on an array of assumptions. Hay et al. (2006) estimate that the return of salt to the sea has varied by a factor of three over the past 540 Ma, reaching maxima in the Upper Cambrian (515 Ma), at the Permian/Triassic boundary (245 Ma), and during the Lower Cretaceous (135 Ma).

Using the inventory of currently sequestered salt and the calculated estimate of salt return, a possible salinity history of sea water for the past 540 Ma can be inferred if the volume history of sea water can be estimated. Fresh basalt on the ocean floors becomes hydrated during subsea

Salinity History of the Earth's Ocean, Figure 1 Salt deposition in the Phanerozoic and estimates of past salinity variations. Ocean salinity declines during deposition of large salt masses. Model estimates by Hay et al. (2006) yield surprisingly high salinity values for the Paleozoic which are not incompatible with values inferred from fluid inclusion measurements by Johnson and Goldstein (1993). Salt masses from estimates by Hay et al. (2006).

weathering and hydrous sedimentary minerals are deposited as the basalt rides tectonic plates to subduction zones. At issue is how much of the hydrated water returns to the surface as it gets progressively heated during subduction. Some models predict a net loss to the mantle over geologic time, so it is not unreasonable to suggest that ocean volumes may have decreased somewhat with time. Combining all these uncertain estimates and models, Hay et al. (2006) have suggested the possible salinity history for the oceans for the past 540 Ma shown in Figure 1. The inferred salinity levels prior to 200 Ma are 50% higher than modern values. Inasmuch as life in the sea is stressed by current salinity values, the idea that Paleozoic life could thrive at such high inferred salinity is likely to be resisted by marine biologists and paleontologists. The amount of brine sequestered during initial deposition and later dissolution remain uncertain and could severely affect such calculated salinity histories. Nevertheless, the provocative Hay et al. (2006) estimates indicate that ocean salinities in the past were likely higher.

Direct salinity measurements in fossil sea water

Tiny fluid inclusions in carbonates or other minerals precipitated directly from ancient seawater may be fossil sea water that could be analyzed for salinity. The difficulty is that the initial precipitates typically undergo dissolution/reprecipitation episodes during subsequent burial and metamorphism. Actual attempts at making this difficult analysis on inferred primary precipitates yield salinities of 31–47‰ at about 500 Ma (Johnson and Goldstein, 1993). These measurements suggest past salinities not too dissimilar from the modern value, but the large error bars do overlap the Hay et al. (2006) estimates (Figure 1). While reliable ancient salinity values remain elusive, it seems demonstrated that significant variations should have occurred in the past 540 Ma and that salinity was likely higher rather than lower in the past.

Salinity history of the early ocean

With regard to deeper time, past salinity can be estimated if it is assumed that the oceans outgassed early in Earth history (Holland, 1978) and that the plate tectonic cycle long ago reached an approximate steady state with regard to hydrosphere cycling through the crust and mantle. Cl^- does not fit readily into any common silicate mineral and thus should have outgassed as HCl along with water following accretion of the Earth. The earliest hydrosphere would thus contain the entire Cl inventory and been at maximum salinity. The only way this high initial salinity can be reduced is by sequestration of salts and brines in the saline giants deposited on long-lived continental cratons. Large continents may have formed shortly after the Earth accreted 4.5 billion years ago (Ga), but recent studies confirm the likelihood that objects in the inner solar system were largely resurfaced by the Late Heavy Bombardment (LHB) at about 3.8–4.0 Ga (Gomes et al., 2005). Continents may have started to reaggregate

following the LHB in the interval between 3.8–2.5 Ga, but the kind of long-lived, continental cratons upon which evaporatively deposited salt and brine could be sequestered following its removal from sea water do not appear until about 2.5 Ga (Rogers, 1996). It follows that all the salt and brine currently lodged on the continents was in the Archean sea following the LHB and prior to the development of these stable cratons.

In the absence of a paleosalinity indicator in the rock record, a reasonable assessment of the earliest salinity could be made if the total amount of salt and brine currently lodged on the continents were known. While the inventory of salt in strata younger than 540 Ma is becoming increasingly better quantified (Figure 1), the amount of salt in older strata is yet to be inventoried. Enormous deposits are known in Neoproterozoic strata (540–800 Ma) across the Middle East, through Pakistan, and into Australia. These apparently accumulated in restricted basins that developed following the breakup of supercontinent Rodinia, analogous to those developed following the breakup of Pangea. The geographic extent of these enormous salt deposits exceeds that of the Cenozoic deposits in the Gulf of Mexico, so it might even be the largest accumulation in Earth history. The amount of subsurface brine associated with the saline giants and with innumerable ancient platform carbonate deposits is also unknown. Land (1995) used estimates of the amount and average salinity of pore fluids to suggest that sequestered brines could hold an amount of salt equal to or greater than that of the rock salt. Adding these amounts of possible total salt and brine currently on the continents back into modern ocean water raises salinity by over a factor of 2. Assuming that the Cl inventory and the oceans were outgassed early in Earth history and have not changed their amounts significantly with time, Archean salinities were therefore much higher and could have exceeded 70‰ (Knauth, 2005).

Implications

The geologic history of salt deposition clearly seems to suggest significant past salinity variations with values possibly much higher than current levels. If so, the impact on biology and biologic evolution must have been significant. An assessment of the paleontologic record in relation to the emerging possible salinity history for the past 540 Ma (Figure 1) remains to be done. The inferred very high salinity of the earliest ocean combined with the probable hot climatic conditions of the early Earth may have limited early marine biologic diversity to the appropriate extremophiles. If the great Neoproterozoic salt deposits were really the first saline giants, the prospect arises that high salinity was prevalent throughout the Precambrian. The great salinity decline likely accompanying deposition of the Neoproterozoic salt combined with declining temperatures associated with probable glaciations may have allowed oxygenation of the ocean for the first time. The Cambrian explosion of life in the sea at 540 Ma may have been, in part, a response of respiring organisms evolving

rapidly in this vast new array of oxygenated marine habitats (Knauth, 2005).

Summary

Salinity is not fixed by any equilibria, feedbacks, or geochemical cycles and appears to have been generally higher in past times. It is apparently a free variable dependent upon the vagaries of intermittent salt (and brine) sequestration on long-lived continental cratons. Ocean salinity declines when the salt and brine accumulate and rises when they are eroded back into the sea. Sequestration seems to have been enhanced following breakup of the two supercontinents in Earth history. These breakups are, in turn, driven by the vagaries of mantle convection. The combination of processes therefore necessary to lower the initial, pre-continent high salinity and to affect the rise and fall of ocean salinity involve a long chain of independent variables. The role of chance and contingency in biologic evolution has long been recognized. The low odds that a rerun of the tape of evolution would yield the same results have been duly noted (Gould, 1990). The same might be said about the evolution of oceanic salinity. Salinity history should therefore probably be added to all those chance occurrences that have likely affected the course of biologic evolution.

SCANNING PROBE MICROSCOPY (INCLUDES ATOMIC FORCE MICROSCOPY)

Michael Hoppert

University of Göttingen, Göttingen, Germany

Synonyms

Atomic force microscopy; Atomic probe microscopy; Force microscopy; Scanning force microscopy

Definition

Scanning probe microscopy uses a nanoscopic probe that is scanned over a solid surface. The interaction between the probe and the surface may be a mechanical or electromagnetic force. The force signal is enhanced and then composed to a force diagram of the surface. Under ideal conditions, an atomic-scale resolution may be achieved.

Introduction

Since their development during the 1970s and early 1980s, scanning probe microscopes (SPMs) have developed into instruments suitable for the analysis of surface topography (and other surface properties) down to near-atomic resolutions. All instruments belonging to this family contain essential components as depicted in [Figure 1](#). In the scanning process, surface material properties are mapped in all three directions. The essential parts of the system are the sharp scanning probe tip, which moves in the *z* direction, a piezoelectric scanner that moves the specimen, or, alternatively, the tip, in the *x/y* directions, and a sensor for tip positioning. Sensor and tip are connected in a feedback loop for the correction of *z* positioning. The *x/y/z* positions are used to generate a topographic image of the specimen. The resolution of SPMs is only limited by the size of the probe tip (or the probe-sample interaction volume). Since the tip apex ends up in one single atom and the piezoelectric actuators execute motions down the range of angstroms, resolutions down to atomic scale are possible. In contrast to electron microscopes, the sample can be observed under ambient conditions, which makes the technique potentially attractive for life science, including geobiological research.

The scanning tunneling microscope (STM)

The scanning tunneling microscope (STM) is the ancestor of all SPMs (Binnig et al., 1982). The specimen needs to be conductive or semiconductive. STM is predominantly used in materials sciences and chemistry. Though not ideally suited for biological specimens, the technique has also been used in life sciences (see, e.g., Guckenberger et al., 1988). The instrument provides a surface topography down to atomic resolution.

STMs use a sharpened conducting tip with a bias voltage (in mV to V-range) applied between the tip and the sample. If the distance between the tip and the sample is large, no current flows. When, however, the tip is brought

Salt Lakes

Definition

Salt: chloride, sulfate, phosphate, carbonate, bicarbonate salts of primarily sodium, magnesium, calcium, and potassium.

Lake: an enclosed body with or without water entering it from a stream, rain, or snow melt.

Ephemeral lake: a lake formed only following rain or snow melt, which dries up during the rest of the year.

Thalassohaline: salts in a lake derived from the evaporation of seawater with the dominant ions of sodium and chloride as found in the ocean.

Athalassohaline: salts in a lake derived from rocks and geological weathering and dominated by magnesium, calcium, and sulfate.

Alkaliphilic lake: also called soda lake. A lake in which the dominant ions are sodium and bicarbonate and carbonate. This causes the lake to have an alkaline pH.

General description of saline lakes

Saline lakes are a natural worldwide phenomenon. They can be found on all continents and in most countries, and they are frequently recognizable by their name – for example, Salt Lick, Salt Lake, Salt Pond, and Salt Marsh. They range in salinity from just above the salt content of sea water (>3.2% salts) to hypersaline lakes (>20% and up to saturation with respect to salts). Examples of saline lakes include, at the lower end, salt lakes in Antarctica, the Caspian Sea, which borders five countries and has

a salinity slightly less than that of seawater, and the Salton Sea in California. At the upper end in salt concentrations are the Dead Sea bordering Israel and Jordan, the soda lakes of North Africa, and Quinghai Lake in China. A general characteristic of saline lakes is that they are terminal lakes, which means that although rivers may flow into them, they have no significant outflow. Therefore, as the water evaporates, the lakes become more salty and in some cases may dry up completely forming salt basins or playas especially in extremely arid environments. In Australia, for example, occasional rains may cause the dry salt basins to become lakes, and these then are called ephemeral salt lakes.

Saline lakes are typically divided into two main types: athalassohaline and thalassohaline. The former refers to lakes which have a different chemical ratio of the main cations from what is found in seawater, while the latter refers to lakes with the cation ratio similar to seawater. [Table 1](#) lists the sodium + potassium ion to calcium + magnesium ion ratios and summarizes the chemical composition of a variety of saline lakes thus showing the wide range of lake types possible.

The data in [Table 1](#) indicate that a subset of the athalassohaline lakes exists. These lakes have a high concentration of carbonate and therefore a high pH. These are the soda lakes or alkaline lakes. They, too, are found worldwide and are described below. No Antarctic lakes are listed in [Table 1](#) because the surface waters are generally only very slightly saline (less than seawater) and it is only with depth, often greater than 10 m, that true saline waters are found. In general, it is the bottom waters that are hypersaline with little turnover to bring the saline waters to the surface. The chemical compositions of Antarctic lakes have been reviewed by Matsubaya et al. (1979).

The reason for the differences in the chemical composition lies in the origins of the various types of lakes. The thalassohaline lakes were generally formed during the

Pleistocene period (Hammer, 1986) and are the result of seawater intrusion before tectonic activity created the mountains which cut the bodies of seawater off from the ocean. Brine springs are formed from the dissolution of salts deposited during evaporation of the seawater. As surface water seeps into the ground, the water percolates downward and eventually encounters the salt, dissolves it, and forms underground saline lakes. These form the basis of often small salty ponds, springs, licks, and rivers.

Athalassohaline lakes are most generally formed by the weathering of rocks by wind, rain, and freshwater and were formed during the Pleistocene period and later by volcanic and faulting activity (Hammer, 1986). These are also terminal lakes, and they are typically close to saturation with respect to salt. They may also be ephemeral – found only occasionally after the rainy season – or permanent containing water year round.

The soda lakes are considered athalassohaline because they were formed from high carbonate rocks due to an absence of rocks of sedimentary origins. Consequently, they have low concentrations of calcium and magnesium ions and high concentrations of carbonate or carbonate complexes (Jones et al., 1998).

Biology of saline lakes

Despite the differences in chemical composition, all saline lakes have certain features in common. In general, fish are not found in lakes with salinities greater than 4‰ (40‰). Two major reasons for this are egg survival (Gerking and Lee, 1980) and loss of osmoregulation (Morris, 1960). One exception is the European sea bass, *Dicentrarchus labrax*, which tolerates salinities up to twice that of seawater (Jensen et al., 1998).

Other eukaryotic organisms are found in the higher salinity lakes, specifically algae, brine flies, and brine shrimp. The diversity of the algae depends on the total salt concentration. At salinities lower than around 10–12‰ salt, a wide variety of diatoms and green algae is found. At salinities greater than 12–15‰ and up to saturation, the main algae are from the genus *Dunaliella*. It is also at these higher salinities that the brine fly and brine shrimp are major biomass contributors. These small eukaryotes provide the food sources for the extensive bird populations that are frequently associated with saline lakes. However, other crustaceans such as the mussel shrimp cannot survive in lakes with salinities greater than 18‰ (Deckker, 1981).

Another group of eukaryotic organisms found throughout the range of saline lakes is the fungi. It is only recently that fungi have been isolated from the higher salinity lakes. The state of our understanding of halotolerant and halophilic fungi was summarized by Frisvad (2005). The presence of protozoans and flagellates in saline lakes has also been reviewed and documented by Hauer and Rogerson (2005) and Cho (2005), respectively.

Just as lower salinities allow for a greater diversity of algae, the same is true for the bacteria. Members of the

Domain *Bacteria* predominate in the salinity range of 3–15‰ salt (Ventosa et al., 1998). Above this, the members of the archaeal kingdom domain, the salt-loving *Halobacteriaceae* become dominant though several members of the domain *Bacteria* grow at these elevated salinities. The predominant *Bacteria* genera in elevated salinities are *Halomonas* and *Salinibacter*. As of August 2007, there were 26 described genera of the haloarchaea and 85 species (Oren et al., 2007), and most, but not all, grow over salinity ranges from approximately 12‰ to close to saturation. Microbes found in most salt lakes are therefore, salt-loving and prefer a circumneutral pH.

Among those haloarchaea genera, the “Natrono-” genera are primarily found in soda lakes. As mentioned above, soda lakes have an alkaline pH; therefore, bacteria which grow under those conditions are considered alkaliphiles (alkaline pH-loving). There are many genera of the kingdom *Bacteria* which also contain genera and species that are alkaliphiles. Thus, all of these bacteria are both salt- and high pH-loving organisms. This distinguishes them from the bacteria described in the previous paragraph.

Halophages are viruses that attack bacteria living in saline lakes. The viruses may incorporate into the bacterial cells or they may cause the lysis of the cells. In either case, halophages, like other bacteriophages, tend to be host-specific and can be found wherever their host organism lives. Dyall-Smith et al. (2005) have recently summarized the state of knowledge about the halophages which are specific for the haloarchaea.

Saline lake sediments

Sediments of saline lakes have been the subject of numerous studies because of the potential for determining stable isotope ratios hence sediment age (Piovano et al., 2004) and using lipid biomarkers (Rontani and Volkman, 2005; Pearson et al., 2007) to indicate the types of biota in the sediments. The exposure history of Dead Sea sediments was determined by examining the various minerals formed within the interstitial waters again improving the understanding of the age and depositional history of saline lake sediments (Yechieli and Ronen, 1997). As the salinity of the overlying water increases, this results in similar increases in the salinity of the interstitial waters within the shallow sediments, and the reverse is also true that decreases in the salinity of the lake due to rainfall or snow melt will decrease the salinity of the pore waters.

These postdepositional changes have also been noted for the alkaline Soda Lake in Washington State in the USA (Mantuani, 1973) and in playa Lake Salines in southeastern Spain (Queralt et al., 1997). Such changes can also affect the biology of the sediments which are anaerobic (low to no oxygen) and are dominated by bacterial mats which can produce sulfides and methane (Miller et al., 1993). These mats are composed of layers of bacteria with the cyanobacteria on the surface and various green and purple sulfur bacteria followed by the sulfate-reducing bacteria that produce the sulfides, and the obligately

anaerobic methane-producing bacteria. More recently, Jioang et al. (2007) have noted, in a core from Lake Chaka on the Tibetan Plateau that the distribution of bacteria within the core is determined by the salinity in the pore waters rather than by the mineralogy, and that the biomass decreased most around 150–200 cm depth and increased slightly at 600 cm with a maximum at 900 cm as determined by phospholipid fatty acid analyses. However, the direct counts remained steady with a slight increase at 900 cm. Most of the organisms identified at these lower depths were anaerobic bacteria, again confirming the importance of oxygen to the types of microorganisms found in any sediment.

Value of saline lakes

Saline lakes are nature preserves and serve as home to extensive permanent and migratory bird populations. Great Salt Lake, Utah, USA, hosts over five million birds annually (and this is true in Africa, Australia, the Caribbean, etc.). They may also act as hatching grounds for flamingoes and other birds at the lower salinities. Thus, saline lakes are important in maintaining the biodiversity of our planet.

A second major value, which is related to the first, is that these environments with their large numbers of microorganisms, brine flies, and brine shrimp provide an important gene pool. Although there are numerous studies on the brine shrimp, very little is known about the brine flies, the algae, or the bacteria found in these lakes. Unknown enzymes, potential antibiotics, drug delivery systems, or mechanisms for adaptation to stress could be present but unknown for lack of research into these areas.

Another value of the lower salinity lakes is their potential for aquaculture. Gamito (1997) successfully showed that the gilthead, *Sparus aurata*, could be grown in the Ria Formosa because of the high benthic productivity (1997). Undoubtedly, there are other fish species that could be successfully grown in the lower salinity saline lakes.

A major economic value of saline lakes is their salt. The ephemeral or dried salt beds are a source of salt to many groups of people. This is especially true in Africa with the Taureg people, and in Tibet which also has salt caravans, in the Atacama region of Chile, in Australia, and in Bolivia to name just a few of the places where salt is harvested from dry saline lake beds.

SALINITY HISTORY OF THE EARTH'S OCEAN

L. Paul Knauth
 Arizona State University, Tempe, AZ, USA

Definition

Salinity refers to the total quantity of dissolved salts in water and is normally about 35 parts per thousand (‰) in today's ocean. Due to problems with making accurate measurements of total salts, salinity is now normally

expressed as a ratio of the electrical conductivity of the seawater to that of a standard concentration of KCl solution. The concentration of the standard solution is set such that the ratio of the approximate average salinity of the ocean today is equal to 35. The previous concentration value (‰) is thus unnecessary, but it is still widely used to highlight the basic meaning of the term. The relative proportions of the dissolved constituents are approximately constant, so the amount of Cl^- , the major component, is a proxy for salinity. Salinity history refers to past changes in the amount of dissolved salts in sea water over geologic time.

Significance

Salinity is an important environmental variable affecting chemical balances and osmotic pressures in all living cells. It particularly affects metazoans, because the amount of dissolved oxygen available for respiration depends on oxygen solubility that decreases as salinity increases. Besides its direct effects on cellular biochemistry, salinity governs the temperature of maximum density of sea water and thus the global thermohaline circulation that influences ecosystems. Models of geochemical cycles yield no constraints on past salinity levels, and reliable geochemical proxies, isotopic records, or other possible indicators of ancient oceanic salinity are currently unknown. However, Na^+ and Cl^- constitute about 85% of the salt in the sea, so the geologic record of halite deposits allows insights into how ocean salinity may have varied with time.

Causes of salinity changes with time

Early ideas that steady riverine input of salt to the oceans causes salinity to increase with time failed to recognize the geologic processes that intermittently cause salt to be removed from the sea and then later released following tectonic uplift. Nor did they correctly assess the probable initial origin of salt in the sea or consider possible small changes in ocean volume over time. Salt in rivers is derived largely from groundwater dissolution of ancient marine salt beds deposited when sea water evaporated under arid conditions in low latitude, geographically restricted arms of the sea. Deposition of these “saline giants” depletes the ocean in salt and thus lowers salinity. Subsequently, these enormous deposits may be tectonically lifted above sea level. Depending upon elevation, descending groundwaters can eventually dissolve the deposit and debouch into streams or lodge as dense, saline brines deeper in the continental subsurface. In addition to the saline giants, carbonate depositional environments in shallow seas that flooded the continents in past times typically contained vast tidal flats and supratidal areas in which sea water intermittently evaporated. Partially evaporated sea water from these environments as well as their ephemeral salts dissolved by falling rains descended into the subsurface and lodged in sedimentary basins even where large saline giants were absent. SEDIMENT DIAGENESIS – BIOLOGICALLY CONTROLLED

Kurt O. Konhauser¹, Murray K. Gingras¹, Andreas Kappler²

¹University of Alberta, Edmonton, Alberta, Canada

²University of Tübingen, Tübingen, Germany

Definition

The biological processes that modify unconsolidated sediment after initial deposition and burial.

Overview

Throughout the sediment column, up to the temperature threshold of life, microbial activity plays an integral role in diagenesis. It is widely recognized that through their various chemoheterotrophic pathways, microorganisms are ultimately responsible for the conversion of organic carbon to CO₂ and CH₄ at temperatures <100°C. Some aerobic bacteria use hydrolytic enzymes to break down complex molecules into simple monomers such as sugars, amino acids, and fatty acids that they can then utilize, while most anaerobes are restricted to simple organic compounds (e.g., acetate, lactate, H₂) that are the by-products of fermentation (Lovley and Chapelle, 1995). Typically, the more labile materials (e.g., proteins, carbohydrates) are degraded in near-surface sediments on time scales of days to years, and more refractory materials (e.g., lipids) are broken down deeper in the sediment on time scales of decades, while the most resistant materials (lignins) are transformed only on timescales of thousands to millions of years. The amount of refractory material left after microbial attack will depend on the nature of the primary producers and the degree of processing that has taken place in the river catchment area or oceanic water column. In the end, for example, <1% of the original material buried into marine sediment may ultimately contribute to the sedimentary organic geochemical record (Emerson and Hedges, 1988).

Pore water and mineralogical changes during diagenesis are directly related to bacterial reduction of soluble (O₂, NO₃[−], SO₄^{2−}, CO₂) or solid-phase (MnO₂ and ferric oxyhydroxides) components in the sediment. The terminal electron accepting processes (TEAPs) that occur at any given layer depends on oxidants that are available and, in the situation when multiple electron acceptors are present (as in the uppermost sediment layers), on the free energy yield of the specific reaction. Thus, the decomposition of freshly deposited organic material in sediments proceeds in a continuous sequence of redox reactions, with the most electropositive oxidants being consumed at, or near the surface, and progressively energetically poorer oxidants being consumed at depth until the labile organic fraction is exhausted and the deeper sediments are left with a composition very different from that of the sediments originally deposited (Figure 1). Inorganic by-products of chemoheterotrophy (e.g., HCO₃[−], Mn²⁺, Fe²⁺, NH₄⁺, NO₂[−], HS[−], HPO₃^{2−} and CH₄) seldom accumulate. Physical and macrofaunal processes will cause the net transport of these reduced species from the deeper layers toward the sediment surface, where residing anaerobic and aerobic chemolithoautotrophic bacteria use them as metabolic reactants. Alternatively, their presence in pore waters may trigger important abiotic reactions between the solid and dissolved phases leading to secondary mineral formation, i.e., cementation.

Oxic zone reactions

The sediment–water interface is the site of most intense heterotrophic activity. Aerobic respiration (Reaction 1) is

Sediment Diagenesis – Biologically Controlled, Figure 1 Idealized pore water and solid-phase profiles based on the successive utilization of terminal electron acceptors during the decomposition of marine sedimentary organic matter. (From Konhauser 2007.)

the first used metabolic pathway for the degradation of organic matter, not only because it has the greatest energy yield per amount of organic carbon oxidized, but the aerobes are equipped with a full suite of extracellular enzymes capable of degrading complex organic polymers into simpler substrates (e.g., cellulose into glucose).

$$\Delta G^0 = -2872 \text{ kJ/mol glucose or } -240 \text{ kJ/2e}^-$$

It is estimated that on a global scale, the majority of all particulate organic carbon (POC) deposited is aerobically respired; the percentage varies among different marine environments, with aerobic respiration accounting for >90% of the organic carbon oxidized in deep sea sediments (e.g., Bender and Heggie, 1984), while O_2 is the TEA in only 45% of coastal marine settings and freshwater lakes (e.g., Jones, 1985).

In marine sediment, one of the primary factors controlling the patterns above is the composition of the organic material and the rate at which it is deposited. Plankton-derived organic matter, rich in lipids and cellulose, exhibit significantly higher reactivities than land-derived organic material consisting of vascular plants rich in lignins (Hedges et al., 1988). Thus, in coastal settings, a significant fraction of POC may be relatively difficult

to decompose. Furthermore, under the high deposition rates characteristic of coastal settings (1 mm year^{-1}), O_2 diffusion is very shallow and the oxic zone may only extend down a few millimeters in depth, although physical stirring of surface sediments by waves and currents, circulation of overlying water through animal burrows that are connected to the sediment–water interface (known as irrigation), and bioturbation of surface sediments may locally increase the depth to several centimeters (e.g., Hammond et al., 1985). Therefore, with high accumulation rates, freshly deposited organic matter passes through the oxic zone on the orders of 1–10s of years, leaving a significant amount of carbon intact to support fermentative and anaerobic heterotrophic populations (Canfield, 1993). By contrast, the influx rate of POC and nutrients decreases with distance from land and water depth. This results in a progressive diminishment of macrofaunal and planktonic species, as well as the benthic bacterial populations, leading to low organic matter accumulation rates in the deep sea. Coupled with the low sedimentation rates associated with the open ocean ($<0.01 \text{ mm year}^{-1}$), the organic fraction will remain exposed to oxygenated waters for thousands of years, leading to almost complete oxidation by O_2 – only the most refractory fractions will remain available for other TEAs in the deeper sediments (Murray and Grundmanis, 1980).

O₂ is also consumed by a vast number of chemolithoautotrophic bacteria that metabolize upwardly diffusing reductants (such as HS⁻, NH₄⁺, Fe(II)). Therefore, as reduced metabolites from anaerobic respiratory pathways diffuse upward, a fraction of the oxygen consumed in the surface layers is diverted away from aerobic respiration, toward reoxidation of the reduced species. As a consequence, the depth of O₂ penetration correspondingly decreases. In fact, some diagenesis models show that the amount of O₂ partitioned to organic carbon oxidation in coastal sediments can be <1%, with nitrification or hydrogen sulfide oxidation comprising the major O₂ sinks (e.g., Blackburn and Blackburn, 1993).

Suboxic zone

Nitrification–denitrification

Nitrogen cycling in aquatic sediments is relatively complex, with nitrate pore water concentrations governed by the balance between nitrification in the oxic zone and denitrification in the suboxic zone. The amount of nitrification is regulated by the concentration of pore water ammonium (NH₄⁺), which largely depends on the C:N ratio of the sedimentary organic carbon being oxidized, and the amount of O₂ penetration (Blackburn and Blackburn, 1993). In the presence of O₂, ammonium is first oxidized to nitrite by ammonium-oxidizing bacteria (e.g., *Nitrosomonas* sp.), and the nitrite is then further oxidized to nitrate by nitrite oxidizers (e.g., *Nitrobacter* sp.). Collectively, these processes (Reaction 2) cause a subsurface peak of nitrate in the pore water (Mortimer et al., 1999).

The opposing processes in marine N-cycling is denitrification (loss of NO₃⁻ to N₂) and nitrate ammonification (loss of NO₃⁻ to NH₄⁺). Denitrifiers most closely resemble aerobic respirers in that they are capable of completely degrading complex organic matter to carbon dioxide (Reaction 3).

$$\Delta G^0 = -2715 \text{ kJ/mol glucose or } -226 \text{ kJ/2e}^-$$

In coastal sediments (and lakes), these bacteria reduce nitrate to negligible levels within 1–10 cm of the sediment–water interface. No nitrate occurs below this depth except where burrows, lined with nitrifying bacteria, irrigate oxygenated water to depths well below the oxic–suboxic boundary (Hansen et al., 1981). In deep sea sediment, the vertical zone of all terminal electron acceptors (TEAs) are expanded, and for nitrate, concentrations may not become negligible until depths of >1 m. Denitrification fluxes range over several orders of magnitude in marine sediments, between values as low as 1 μmol m⁻² day⁻¹ in deep sea sediments (Bender and Heggie, 1984)

and over 1 mmol m⁻² day⁻¹ in some estuarine and coastal waters (e.g., Devol, 1991).

The flux of N₂ escaping from sediments is often higher than predicted biological or inorganic denitrification rates based solely on pore water nitrate concentrations. This means that in the sediments, excess N₂ is being formed independent of a nitrate intermediate. One way this occurs is through the anammox process, where shunting nitrogen directly from ammonium to N₂ (Reaction 4) can promote ammonium deficiencies in sediments where this process plays a key role in nitrogen cycling (Thamdrup and Dalsgaard, 2002).

Ammonium can also react inorganically with MnO₂ to form N₂ instead of nitrate (Reaction 5). The Mn(II) formed in this reaction is biologically oxidized by Mn(II)-oxidizing bacteria (see below), with O₂ as the TEA, generating more reactive MnO₂ to continue the oxidation of the soluble ammonium (Luther et al., 1997). Field evidence suggests that this reaction can outcompete the direct oxidation of NH₄⁺ by O₂ to NO₃⁻ in Mn-rich coastal sediments, and in doing so, potentially account for 90% of N₂ formation. In essence, this process short-circuits the traditionally considered nitrification–denitrification process.

Manganese cycling

Detrital mineral phases that survive transport and deposition are for the most part an unreactive component of the bottom sediment. The oxides and hydroxides of manganese and iron are the exceptions. These phases are stable under the oxygenated conditions encountered in the water column, but they quickly become unstable after burial below the oxic layers of sediment. Following denitrification, reduction of Mn(IV) oxides (typically written as MnO₂) to dissolved Mn²⁺ becomes the most energy-efficient bacterial respiratory process (Reaction 6).

$$\Delta G^0 = -558 \text{ kJ/mol acetate or } -139 \text{ kJ/2e}^-$$

In most sediments, the limited amount of manganese (and iron) oxides deposited in sediment, as well as the slower rates of burial of these oxides compared to the downward diffusion of O₂, NO₃⁻ and SO₄²⁻, generally makes their reduction of minor importance (<10%) in terms of the amount of total organic carbon oxidized (Burdige, 1993). There are, however, exceptions to this generalization, i.e., some lakes and marine hydrothermal settings where high rates of metal oxide reduction are driven by a combination of relatively high metal inputs and active macrofaunal activity that mix suboxic sediment with

oxygenated bottom waters, thereby reoxidizing dissolved Mn^{2+} (and Fe^{2+}) to MnO_2 or $\text{Fe}(\text{OH})_3$ (Aller, 1990).

In typical marine sediments, the concentration of Mn^{2+} is negligible at the sediment surface, but at some depth between the NO_3^- maximum and zero NO_3^- , it begins to increase toward its maximum values. Despite forming near the base of the nitrate reduction zone, its concentration is never highest at that depth because the $\text{Mn}(\text{II})$ that diffuses upward is biologically reoxidized and precipitated as fresh MnO_2 at the sediment surface, suggesting that the TEA can be either nitrate or oxygen (Froelich et al., 1979). A characteristic feature of $\text{Mn}(\text{II})$ oxidation is the upward convexity of the pore water Mn^{2+} profile and the discrete layer of MnO_2 forming at the base of the oxic zone (recall Figure 1). By contrast, downward diffusion of $\text{Mn}(\text{II})$, and its reaction with HCO_3^- , most commonly results in the formation of manganese carbonates, such as rhodochrosite (MnCO_3).

Iron cycling

Below the zone of dissimilatory manganese reduction, and at the depth of complete nitrate removal from pore waters, is where $\text{Fe}(\text{III})$ reduction takes place (Reaction 7). Ferrihydrite [$\text{Fe}(\text{OH})_3$] is the least crystalline, most reactive, and easily reducible iron oxide phase, with rates of $\text{Fe}(\text{III})$ reduction in sediment declining rapidly with depth as these poorly crystalline phases become depleted (Lovley and Phillips, 1986).

$$\Delta G^0 = -337 \text{ kJ/mol acetate or } -84 \text{ kJ}/2\text{e}^-$$

Despite the lower reactivity of crystalline phases, in sediment where ferrihydrite has either been depleted or where crystalline iron oxides are inherently more abundant, the latter can serve as significant source of reducible iron that couples the oxidation of buried organic material. According to experimental observations, $\text{Fe}(\text{III})$ -reducing microorganisms developed three different strategies to cope with the difficulty of transferring electrons from the cell to the surface of a barely soluble electron acceptor (see Lovley et al., 2004 for review). First, physical contact between the cell surface and ferric iron allows direct delivery of electrons. Second, iron chelators increase the solubility of $\text{Fe}(\text{III})$ and hence, alleviate the need for $\text{Fe}(\text{III})$ reduction. Third, electron-shuttling compounds transfer electrons from the cell to $\text{Fe}(\text{III})$ oxide surface without the necessity of physical contact between cells and mineral. Considering the complexity of natural environments and the wealth of microbial capabilities, it is not surprising that different organisms, as well as single organisms, developed different strategies in order to reduce diverse $\text{Fe}(\text{III})$ compounds under varying conditions. For example, some evidence indicates that *Geothrix fermentans* produce and release both $\text{Fe}(\text{III})$ chelators and electron

shuttles (Nevin and Lovely, 2002). Furthermore, studies on *Geobacter* sp. indicate that different cellular compounds are involved in reduction of dissolved $\text{Fe}(\text{III})$ -citrate and barely soluble ferrihydrite (e.g., Leang et al., 2005).

The reduction of ferric iron minerals increases the concentration of $\text{Fe}(\text{II})$ in suboxic sediment pore waters, with a peak in concentration at the boundary between the $\text{Fe}(\text{III})$ and sulfate reduction zones. Some of this ferrous iron may diffuse upward to be reoxidized to ferric hydroxide inorganically by either NO_2^- , MnO_2 , or O_2 (e.g., Myers and Nealson, 1988), and it is likely that in some lakes with near-surface sediment, phototrophic $\text{Fe}(\text{II})$ oxidation should take place. Some $\text{Fe}(\text{II})$ also precipitates as mineral phases. In iron-rich sediments, the high reactivity of Fe^{2+} and the general availability of HCO_3^- in suboxic and anoxic pore waters tend to cause ferrous iron to precipitate quickly as micritic cement in the form of siderite (FeCO_3). By contrast, when sulfate reduction rates exceed $\text{Fe}(\text{III})$ reduction rates (see below), enough HS^- is produced to react preferentially with any ferrous iron to precipitate iron monosulfide minerals instead (FeS has lower solubility than FeCO_3). Therefore, the precise juxtaposition of iron reduction and sulfate reduction in marine sediments controls the formation of siderite and/or pyrite (e.g., Coleman, 1985). The formation of vivianite [$\text{Fe}_3(\text{PO}_4)_3$] in many ways resembles that of siderite, namely $\text{Fe}(\text{II})$ concentrations must exceed those of HS^- . It also requires that soluble phosphate is made available through oxidation of organic matter, the dissolution of phosphorous-bearing solid phases, or through reduction of phosphorous-adsorbing $\text{Fe}(\text{III})$ oxides (Krom and Berner, 1980).

Anoxic zone

Sulfate reduction

Below the suboxic layers is a highly reducing, oxygen-free zone under which sulfate reduction predominates. In marine sediments, this is the principal process by which simple fermentation products are oxidized (Reaction 8), accounting for approximately 50% of the carbon oxidation in coastal marine sediments (Jørgensen, 1982), but <10% in deep sea and freshwater environments (Bender and Heggie, 1984; Jones, 1985).

$$\Delta G^0 = -49 \text{ kJ/mol acetate or } -12 \text{ kJ}/2\text{e}^-$$

Its relative importance in marine environments compared to freshwater environments is based simply on the higher concentrations of dissolved SO_4^{2-} (~28 mM) at the sediment–water interface, some 50 times greater than the combined sum of all other electron acceptors with higher electrode potentials. Moreover, external electron acceptors that yield more energy than SO_4^{2-} typically disappear within the first few centimeters of sediment depth, leaving sulfate as the dominant TEA for most of the sediment column (D'Hondt et al., 2002).

The rates of dissimilatory sulfate reduction are proportional to the quantity and reactivity of organic matter entering the anoxic sediments – the greater the amount of aerobic decomposition, the less labile organic matter remains available for sulfate reduction, and the more refractory the residual material becomes (Westrich and Berner, 1984). As a result of natural variations in the above, sulfate reduction rates in marine sediments can vary by six orders of magnitude, with the highest in rapidly deposited coastal and lagoonal sediments, where it occurs just below the sediment–water interface ($>1 \text{ mM cm}^{-2} \text{ year}^{-1}$) and at the lowest levels in deep sea sediments, where rates may be $<10^{-5} \text{ mM cm}^{-2} \text{ year}^{-1}$ (Canfield, 1993).

The product of sulfate reduction is hydrogen sulfide, and as mentioned above, can lead to the formation of iron sulfide minerals. The amount and reactivity of the detrital iron phases dictate the amount of pyrite that will form, commonly referred to as the “degree of pyritization.” In slowly accumulating sediments (i.e., the deep sea), little labile organic matter is buried, sulfate reduction rates are slow, less HS^- is available for reaction with detrital iron, so less ferric iron is eventually converted to pyrite. Since the saturation state of the pore waters with respect to iron monosulfides controls the pore water concentrations of dissolved iron and sulfide, limited HS^- means that pore water Fe(II) will increase in concentration. By contrast, in rapidly accumulating sediments, more labile organics are buried, near-surface sulfate reduction rates are high, HS^- is abundant, and more of it is available for reaction with dissolved Fe(II) and solid-phase ferric iron (Berner and Raiswell, 1983). Nonetheless, not all ferric iron phases are pyritized because some ferric iron minerals react only very slowly with dissolved sulfide, and complete pyritization becomes impossible in the time span over which sulfate reduction occurs in the sediment (Canfield et al., 1992).

Only a fraction of the HS^- that forms via bacterial sulfate reduction is actually precipitated as pyrite sulfur (Berner, 1982). Instead, some 90% of the HS^- is reoxidized to sulfate. Although O_2 , NO_3^- , and Mn(IV)- or Fe(III)-oxides are the ultimate oxidants in sedimentary systems, there exists a dynamic S-subcycle that involves a number of sulfur intermediate products, with thiosulfate appearing to be the most significant (Jørgensen, 1990). In addition, some of the HS^- that ultimately escapes the thio-sulfate subcycle provides a useable source of reducing power for various chemolithoautotrophs, most of which gain energy from oxidizing sulfide, with O_2 as the TEAP (Reaction 9).

Methanogenesis

The terminal step in the anaerobic degradation of organic material is methanogenesis (Reactions 10 and 11). As the least energetically favorable process of organic

degradation, the reaction product, methane (CH_4), actually stores a major part of the energy available for aerobically respiring species, i.e., methanotrophs.

$$\Delta G^0 = -31 \text{ kJ/reaction}$$

$$\Delta G^0 = -34 \text{ kJ/reaction}$$

On average, methanogenesis is responsible for 5–10 times less organic carbon degradation than sulfate reduction, and it is only important in sediments where a significant amount of relatively fresh organic material is delivered rapidly enough to pass through the sulfate reduction zone that it takes on any prominence (Canfield, 1993). Indeed, methane does not accumulate in sediments until more than 90% of the dissolved sulfate has been reduced (Martens and Berner, 1974). This is unsurprising given that the growth of methanogens is inhibited by SRBs, because the latter have a higher affinity for the oxidizable substrates than do the former (Lovley et al., 1982). In other words, methanogens prosper when subsurface activity of SRBs is high and pore water SO_4^{2-} becomes diminished.

The CH_4 generated by methanogens in the underlying sediment subsequently diffuses upward toward the sulfate-rich sediments, where it serves as an electron donor in the sulfate–methane transition zone (SMTZ) (Reaction 12).

In some marginal marine sites, it has been estimated that nearly 100% of the downward SO_4^{2-} flux and the upward CH_4 flux can go toward anaerobic CH_4 oxidation. Comparison of these fluxes to open ocean sites even suggests that anaerobic methane oxidation might be the dominant sink for sulfate in marine sediments relative to organic carbon oxidation (D'Hondt et al., 2002). The diffusive flux of CH_4 upward is usually inadequate to completely reduce pore water sulfate, and hence, accumulate above the SMTZ. Yet, it has been observed in some rapidly depositing shallow water sediments that methane saturates pore waters and ultimately may escape the sediment by bubble ebullition, without complete oxidation by sulfate (Martens and Klump, 1984).

Sediment hydrogen concentrations

As discussed above, the dominant terminal electron accepting pathways in sediments are generally segregated into distinct zones based on the potential thermodynamic yield of the various metabolic processes. Yet, on a purely thermodynamic basis, reactions yielding less energy should also take place as long as they are energetically favorable. Instead, the segregation can be more accurately explained by competition between different types of

microorganisms for electron donors, such as the fermentation products H_2 and acetate (Lovley and Klug, 1986). Accordingly, microorganisms utilizing electropositive TEAs effectively maintain H_2 concentrations below the capabilities of microorganisms using TEAs that yield less energy, and it is only when the electropositive TEA becomes depleted that the next most electropositive TEA controls the H_2 concentrations in the pore water system (Lovley and Goodwin, 1988). In pore waters, this translates into distinct H_2 concentration gradients for each particular metabolism and a threshold level below which H_2 cannot be further metabolized. When nitrate and manganese reductions are the dominant terminal electron accepting pathways, pore water hydrogen concentrations are extremely low (<0.05 nM), with increasing levels through iron reduction (0.2 nM), sulfate reduction (1–1.5 nM), and methanogenesis (7–10 nM). Acetate concentrations follow a similar pattern (Chapelle and Lovley, 1992).

This pattern of H_2 and acetate competition can be ascribed to the physiological capabilities of the microorganisms growing in the sediments. Microorganisms that use amorphous ferric hydroxide as their TEA can metabolize H_2 or acetate to concentrations lower than those that can be utilized by sulfate reducers, and the sulfate reducers can metabolize the same substrates to concentrations below those usable by methanogens (Lovley and Phillips, 1987). These findings are consistent with observations of sediments where sulfate is not reduced, and methane is not produced until the reducible ferric iron minerals have been converted to Fe(II). Given the pattern above, it is not surprising then that the availability of NO_3^- or Mn(IV) oxides diminishes the magnitude of Fe(III) reduction in suboxic sediment, and under such conditions, some of the Fe(III) reducers may even switch over to nitrate or manganese reduction when H_2 becomes limiting for them under their normal mode of growth (Lovley and Phillips, 1988; diChristina, 1992).

Macroscopic biological influence on diagenesis

On the seafloor, recently deposited sediment is subject to grazing, burrowing, and particle reworking by relatively large animals moving over the surface of the sediment and the more numerous small organisms and microorganisms living within the upper layers of sediment. This influence may extend several decimeters (and even meters) below the sediment–water interface, but their effect is largely concentrated in the uppermost 20 cm. The benthos are typically inhibited when (1) the particulate organic supply is too low; (2) when the sediment is too fine-grained and compacted to provide sufficient space for them to live, (3) when O_2 levels reach values <0.2 mg l^{-1} , and (4) when strong ebb and current flows quickly redistribute sediment for burrows to become established (e.g., Van Cappellen and Gaillard, 1996).

Burrowing organisms biomechanically and geochemically alter sediments – a process generally referred to as

bioturbation – in spatially intricate ways. Biomechanical modification includes the redistribution of grain sizes and the modification of grain size and sediment cohesiveness. It also impacts on the organic properties of the sediment because grazing causes greater disintegration of intact organic remains, leading to higher surface areas for microbial oxidation, while burrowing mixes fresh organic matter with older, more decomposed materials, causing enhanced degradation of the latter. Ingestion of refractory organic carbon may lead to excretion of more labile fecal pellets (Lee, 1992). The style of biomechanical deformation can be variable depending on the intrusive process employed by the burrowing animal. In clastic sediments, the redistribution of sediment grain sizes strongly influences the arrangement of permeability pathways, thereby exerting a control on the flux of pore water near, and within, preserved burrows. Through abrasion and ingestion, carbonate sediments are prone to (biogenic) grain-size reduction. This provides a more reactive medium for diagenetic fluids to react with.

The biochemical modification of sediment is the result of local compositional heterogeneity imposed by biogenic structures. This includes an increase in the surface area at the sediment–water interface, which in turn, increases the rate and amount of chemical exchange between the sediment, the pore water, and the water column. For instance, irrigation of worm burrow tubes with oxygenated seawater results in increased downward and lateral diffusion of O_2 into surrounding sediment and concomitantly the loss of sulfur from the sediment by oxidation of pyrite and enhanced diffusive loss of HS^- (Bernier and Westrich, 1985). Subsurface flushing with oxygenated waters also influences nitrification, Mn(II)- and Fe(II)-oxidation patterns. In the case of iron cycling, as long as ferric iron persists, phosphate remains adsorbed to the oxide surface and is thus unavailable to the pore waters. Meanwhile, the incorporation of concentrated (and typically labile) organic material in the form of mucus or feces not only provides an oxidizable substrate for the microbial communities, but also leads to concentration of metals in, and adjacent to, burrow linings as sorbed cations or as metal oxyhydroxide, sulfide, or phosphate coatings (Over, 1990). These metals may then serve as nucleation sites for authigenic mineral formation, which provides a variable chemical stock for diagenetic fluids to interact with (i.e., dolomitization, cementation).

Collectively, the imposition of burrows at the sediment–water interface perturbs the generally accepted geochemical zonations within (subaqueous) sediments, proffering a complex distribution of geochemical zones (Aller, 1980).

Summary

Microorganisms are integral to the chemical and physical changes sediment undergoes during the process of diagenesis. Through various chemoheterotrophic pathways, microorganisms are ultimately responsible for the

conversion of organic carbon to CO_2 (or CH_4) through the coupled reduction of dissolved (O_2 , NO_3^- , SO_4^{2-} , CO_2) or Fe(III)/Mn(IV) oxyhydroxides in the sediment. The inorganic by-products of chemoheterotrophy (HCO_3^- , Mn^{2+} , Fe^{2+} , NH_4^+ , NO_2^- , HS^- , HPO_4^{2-} , CH_4) are either transported from deeper sediment toward the seafloor, where residing chemolithoautotrophic bacteria use them as reactants in their metabolism, or their presence in pore waters may trigger secondary mineral precipitation and cement formation. Macrofauna also contribute to diagenetic reactions through their bioturbating activity. This includes the direct effects of burrowing and mixing of fresh sediment with older sediment, grazing and disintegration of intact organic remains, and the excretion of labile fecal pellets. Indirectly, they influence the solid-phase and pore water properties of sediment by increasing the transport of redox-active elements across the sediment–water interface.

Definition

Selenium, element 34, is a metalloid in row VIB of the periodic table. The main oxidation states are selenide (−2), elemental selenium (0), selenite (+4), and selenate (+6). Selenate and selenite are found in the oxic zone, while Se(0) is more abundant in the anoxic zone. Although hydrogen selenide may be produced by microorganisms, it is highly toxic. Se(−II) is more often found as organoselenium in the form of selenoproteins. The common methylated species (e.g., dimethylselenide, dimethyldiselenide) are volatile. Selenium can be a substitute for sulfur and is often found as metal selenide (e.g., Clausthalite, Crookesite). Selenium occurs in eight stable isotopes, the most common of which are Se80 (~50%) and Se78 (~24%), and nine radioactive isotopes.

The microbial oxidation of selenium is a slow process, whereas the dissimilatory reduction of selenate via selenite to Se(0) is rapid (Dowdle and Oremland, 1998). Selenate and selenite may also be methylated, and Se(0) can be further reduced to selenide (HSe^{−1}). Se(0) is insoluble, and bacteria form “nanospheres” of roughly uniform diameter (0.2–0.3 μm) (Oremland et al., 2004). These nanospheres can occur inside the cytoplasm or on the outside of the cell wall and may exhibit measurable isotope fractionation (⁸⁰Se/⁷⁶Se of −8.0‰ to −12.4‰) (Herbel et al., 2000). Selenium may be assimilated via the sulfur assimilation pathway.

Selenium is an essential element primarily needed for the synthesis of selenocysteine and selenomethionine (as reviewed in Stolz et al., 2006). Selenocysteine (Sec, U) is the 21st amino acid (encoded by UGA) and is found in a number of enzymes (e.g., glycine reductase, formate dehydrogenase). Sec requires four specific gene products: SelA, selenocysteine synthase; SelB, a special translation factor; SelC, a Sec-specific tRNA (tRNA^{Sec}); and SelD, the selenophosphate synthase. SelB recognizes the alternative coding of UGA for selenocysteine aided by a stem loop structure in the mRNA. The selenocysteine insertion sequence, or SECIS, is found within the 3′ untranslated region of the mRNA in archaea and eukaryotes and immediately downstream of the UGA codon in bacteria.

Over 20 species of selenate respiring prokaryotes are known and include members of the Crenarchaeota, low and high G + C Gram-positive bacteria, Halanaerobacter, and beta-, gamma-, and epsilon-proteobacteria; however, only a few species respire selenite. The respiratory selenate reductase (Ser) from *Thauera selenatis* is a heterotrimer (SerA, SerB, SerC) and belongs to the

Selenium occurs in eight stable isotopes, the most common of which are Se80 (~50%) and Se78 (~24%), and nine radioactive isotopes.

The microbial oxidation of selenium is a slow process, whereas the dissimilatory reduction of selenate via selenite to Se(0) is rapid (Dowdle and Oremland, 1998). Selenate and selenite may also be methylated, and Se(0) can be further reduced to selenide (HSe^{−1}). Se(0) is insoluble, and bacteria form “nanospheres” of roughly uniform diameter (0.2–0.3 μm) (Oremland et al., 2004). These nanospheres can occur inside the cytoplasm or on the outside of the cell wall and may exhibit measurable isotope fractionation (⁸⁰Se/⁷⁶Se of −8.0‰ to −12.4‰) (Herbel et al., 2000). Selenium may be assimilated via the sulfur assimilation pathway.

Selenium is an essential element primarily needed for the synthesis of selenocysteine and selenomethionine (as reviewed in Stolz et al., 2006). Selenocysteine (Sec, U) is the 21st amino acid (encoded by UGA) and is found in a number of enzymes (e.g., glycine reductase, formate dehydrogenase). Sec requires four specific gene products: SelA, selenocysteine synthase; SelB, a special translation factor; SelC, a Sec-specific tRNA (tRNA^{Sec}); and SelD, the selenophosphate synthase. SelB recognizes the alternative coding of UGA for selenocysteine aided by a stem loop structure in the mRNA. The selenocysteine insertion sequence, or SECIS, is found within the 3′ untranslated region of the mRNA in archaea and eukaryotes and immediately downstream of the UGA codon in bacteria.

Over 20 species of selenate respiring prokaryotes are known and include members of the Crenarchaeota, low and high G + C Gram-positive bacteria, Halanaerobacter, and beta-, gamma-, and epsilon-proteobacteria; however, only a few species respire selenite. The respiratory selenate reductase (Ser) from *Thauera selenatis* is a heterotrimer (SerA, SerB, SerC) and belongs to the

DMSO reductase family of molybdenum enzymes. Two different methyltransferases have been identified. Bacterial thiopurine methyltransferase converts selenite and selenocysteine to dimethylselenide and dimethyldiselenide. MmtA (the calicheamicin-like methyltransferase) produces dimethylselenide and dimethyldiselenide from selenite and selenocysteine (as reviewed in Stolz et al., 2006).

SHALES

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

Historically, the term shale has been used to describe fine-grained sedimentary rocks of largely terrigenous derivation, dominated by mud-size particles (0.06 mm and smaller) and containing appreciable quantities (several 10%) of clay minerals. The definition of the term has been a subject of debate (Potter et al., 2005) because of the closely allied terms mud and clay for which competing definitions may emphasize grain size, mineralogy (clay dominated), or physical properties (plasticity). In place of shale, the term mudstone is also used widely and describes the same compositional spectrum of sedimentary rocks. Because shales span the clay–silt boundary, a good many rocks that are identified as siltstones in the literature also qualify as shales (and vice versa). Although the term shale traditionally had a “terrigenous” connotation, shales that accumulated in sediment starved settings may to more than 50% consist of microbially induced early diagenetic cements (calcite, dolomite, ferroan carbonates, silica, authigenic clays, and iron sulfides), organic matter, and biogenic debris (fish bones, microfossils) upon close inspection. One could argue that the term “biogenic” would be more appropriate for these rocks.

Thus, categorizing shales is by no means a trivial exercise and the various classification schemes in existence (e.g., Ingram, 1953; Dunbar and Rodgers, 1957; Folk,

1965; Picard, 1971; Lewan, 1979; Blatt et al., 1980; Lundegard and Samuels, 1980; Potter et al., 1980; Stow and Piper, 1984; Macquaker and Adams, 2003) leave much to be desired. Many fine-grained sedimentary rocks contain variable amounts of a fine-grained carbonate component and it is common practice to use the terms shale and mudstone for rocks with less than 50% carbonate (Potter et al., 2005). Beyond that arbitrary cut-off the terms marl, micrite, limestone, and dolostone are most commonly used. The classification scheme proposed by Macquaker and Adams (2003), however, also includes fine-grained materials of non-terrigenous origin. The books by Potter et al. (1980, 2005) and Schieber et al. (1998) provide further information on this, as well as other topics concerning shales.

Fundamentally, shales span such a large compositional and textural spectrum that a comprehensive and meaningful classification will only be possible when we can build on a much larger body of case studies than currently available. At present it is probably pointless to agonize over the actual names given to shale types encountered in a given study. What matters primarily is that the rocks be dominantly fine grained, and that we report as accurately as possible their composition, texture, and fabric. The latter two are indispensable for meaningful descriptions of shales because they convey key insights into their transport and deposition (Schieber, 1999a; Schieber et al., 2007).

Significance of shales for geobiology

Although still understudied when compared to sandstones and carbonates (Schieber and Zimmerle, 1998), shales nonetheless are geologically important for multiple reasons. They constitute by volume two thirds of the sedimentary rock record and once examined systematically will contribute much to a better understanding of Earth history and the evolution of life. Because overall they accumulate slower than sandstones or carbonates, as much as 90% of geologic time recorded in sedimentary rocks may be preserved in shales.

Shales are an excellent matrix for fossil preservation, and contained fossils are comparatively easy to extract for study. Because their low permeability limits chemical exchange and access by oxygen, metastable skeletal minerals (e.g., aragonite) and even soft tissues may be preserved. It is not by accident that many of the world's most scientifically significant sites of fossil preservation (Fossil Lagerstätten; Seilacher et al., 1985) are found in shale successions. Notable examples are the Cambrian Burgess Shale (Morris, 1998), the Devonian Hunsrück Slate (Bartels et al., 1998), the Jurassic Posidonia Shale (Kauffman, 1978), and the Messel oil shale deposit (Wuttke, 1983). Preservation of fossils carries much valuable information, particularly in the case of marine shales. Fossils are useful because taphonomy (the study of organismal decay over time), spatial distribution of fossils, fossil diagenesis, morphological attributes of fossils

DMSO reductase family of molybdenum enzymes. Two different methyltransferases have been identified. Bacterial thiopurine methyltransferase converts selenite and selenocysteine to dimethylselenide and dimethyldiselenide. MmtA (the calicheamicin-like methyltransferase) produces dimethylselenide and dimethyldiselenide from selenite and selenocysteine (as reviewed in Stolz et al., 2006).

SHALES

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

Historically, the term shale has been used to describe fine-grained sedimentary rocks of largely terrigenous derivation, dominated by mud-size particles (0.06 mm and smaller) and containing appreciable quantities (several 10%) of clay minerals. The definition of the term has been a subject of debate (Potter et al., 2005) because of the closely allied terms mud and clay for which competing definitions may emphasize grain size, mineralogy (clay dominated), or physical properties (plasticity). In place of shale, the term mudstone is also used widely and describes the same compositional spectrum of sedimentary rocks. Because shales span the clay–silt boundary, a good many rocks that are identified as siltstones in the literature also qualify as shales (and vice versa). Although the term shale traditionally had a “terrigenous” connotation, shales that accumulated in sediment starved settings may to more than 50% consist of microbially induced early diagenetic cements (calcite, dolomite, ferroan carbonates, silica, authigenic clays, and iron sulfides), organic matter, and biogenic debris (fish bones, microfossils) upon close inspection. One could argue that the term “biogenic” would be more appropriate for these rocks.

Thus, categorizing shales is by no means a trivial exercise and the various classification schemes in existence (e.g., Ingram, 1953; Dunbar and Rodgers, 1957; Folk,

1965; Picard, 1971; Lewan, 1979; Blatt et al., 1980; Lundegard and Samuels, 1980; Potter et al., 1980; Stow and Piper, 1984; Macquaker and Adams, 2003) leave much to be desired. Many fine-grained sedimentary rocks contain variable amounts of a fine-grained carbonate component and it is common practice to use the terms shale and mudstone for rocks with less than 50% carbonate (Potter et al., 2005). Beyond that arbitrary cut-off the terms marl, micrite, limestone, and dolostone are most commonly used. The classification scheme proposed by Macquaker and Adams (2003), however, also includes fine-grained materials of non-terrigenous origin. The books by Potter et al. (1980, 2005) and Schieber et al. (1998) provide further information on this, as well as other topics concerning shales.

Fundamentally, shales span such a large compositional and textural spectrum that a comprehensive and meaningful classification will only be possible when we can build on a much larger body of case studies than currently available. At present it is probably pointless to agonize over the actual names given to shale types encountered in a given study. What matters primarily is that the rocks be dominantly fine grained, and that we report as accurately as possible their composition, texture, and fabric. The latter two are indispensable for meaningful descriptions of shales because they convey key insights into their transport and deposition (Schieber, 1999a; Schieber et al., 2007).

Significance of shales for geobiology

Although still understudied when compared to sandstones and carbonates (Schieber and Zimmerle, 1998), shales nonetheless are geologically important for multiple reasons. They constitute by volume two thirds of the sedimentary rock record and once examined systematically will contribute much to a better understanding of Earth history and the evolution of life. Because overall they accumulate slower than sandstones or carbonates, as much as 90% of geologic time recorded in sedimentary rocks may be preserved in shales.

Shales are an excellent matrix for fossil preservation, and contained fossils are comparatively easy to extract for study. Because their low permeability limits chemical exchange and access by oxygen, metastable skeletal minerals (e.g., aragonite) and even soft tissues may be preserved. It is not by accident that many of the world's most scientifically significant sites of fossil preservation (Fossil Lagerstätten; Seilacher et al., 1985) are found in shale successions. Notable examples are the Cambrian Burgess Shale (Morris, 1998), the Devonian Hunsrück Slate (Bartels et al., 1998), the Jurassic Posidonia Shale (Kauffman, 1978), and the Messel oil shale deposit (Wuttke, 1983). Preservation of fossils carries much valuable information, particularly in the case of marine shales. Fossils are useful because taphonomy (the study of organismal decay over time), spatial distribution of fossils, fossil diagenesis, morphological attributes of fossils

Shales, Figure 1 (a) TEM micrograph of modern mud from the continental slope off northern California at a burial depth of 5 cm. Illustrates the spatial relationships of a colony of bacteria (bc), its extracellular polymeric substances (ep), and the surrounding sediment matrix of clay (c) and organic matter (o). Scale bar represents 1 μm . (b) TEM micrograph of a modern mud from Eckernförde Bay, Germany. Shows the relationships between bacteria (b), their extracellular polymeric substances (ep), and the surrounding sediment matrix of clay (c), and organic matter (o). Scale bar represents 0.5 μm . (From Ransom et al., 1999.)

(e.g., reflecting adaptation to substrate conditions), fossil assemblages and comparison to modern counterparts, and paleocommunities (paleoecology) all can provide a wealth of information about the deposition of a shale succession (e.g., Allison, 1988; Brett and Allison, 1998).

Freshly deposited muds, the sediments destined to become shales after compaction, have an enormous internal surface area. Depending on the assumptions about particle geometry and water content, one can readily estimate that a liter of watery mud should have an internal surface area on the order of several hundred square meters (e.g., Fenchel, 1970). That is enough space to provide habitat for trillions (10^{12}) of microbial cells (Figure 1).

Deposition of shales

The sedimentology of shales has made progress over the past decades (Potter et al., 2005), and sedimentologists are gradually learning to appreciate the utility of the many small scale sedimentary structures observable in shales (e.g., Schieber, 1989, 1990a,b, 1999a; O'Brien and Slatt, 1990). When studied in polished slabs and petrographic thin sections, a wealth of information about depositional conditions and history can be gleaned from most shales (Figure 2).

Laminae are the most typically observed sedimentary feature in shales. They show a large range in thickness and lamination styles (even, discontinuous, lenticular, wrinkled etc.), and these may represent conditions that include quiet settling, sculpting of the sediment surface by bottom currents, and growth of microbial mats

Shales, Figure 2 Line drawing that summarizes features observed in a mudstone from the late Devonian Sonyea Group in New York. (From Schieber 1999a.) M = mica; Q = quartz; py = pyrite.

respectively (Schieber, 1986, 1999b). Internal lamina features, e.g., grading (a), random clay orientation (b), preferred clay orientation (c), sharp basal contacts (d), and sharp top contacts (e) may be interpreted as indicative of (a) event-sedimentation (e.g., floods, storms, turbidites), (b) flocculation or sediment trapping by microbial mats, (c) settling from dilute suspension, (d) current flow and erosion prior to deposition, and (e) current flow and erosion/reworking after deposition (Schieber, 1990a,b). Due to somewhat larger grain size, silt laminae are the most readily observed lamina type in shales and may imply

somewhat more energetic conditions. Examples are density currents (grading, fading ripples), storm reworking and transport (graded rhythmites), wave winnowing (fine even laminae with scoured bases), and bottom currents (silt layers with sharp bottom and top). Gradual compositional changes between, e.g., clay and silt dominated laminae are another commonly observed feature, and are suggestive of continuous (although slow) deposition, possibly from deltaic sediment plumes and shifting nepheloid flows.

For many years conventional wisdom has held that parallel laminae in shales are the result of settling from slow moving or still suspensions, and the common assumption was that this reflects distal deposition in comparatively deep water with only minor current activity. Recent flume experiments, however, have demonstrated conclusively that muds can be deposited from swift moving currents that are competent enough to move sand in bedload (Schieber et al., 2007). This occurs because muds have a strong tendency to flocculate, regardless of exact particle mineralogy and water composition. The floccules travel in bedload and form migrating ripples (Figure 3) that build up a contiguous mud bed if sediment supply is sufficient. In spite of accumulation via lateral accretion, after compaction these muds have a parallel laminated appearance, just like many shales in the rock record (Figure 4; Schieber et al., 2007). Obviously, it will be difficult from now on to ascribe a quiet, deep water setting to a laminated shale without corroborating evidence (e.g., paleoecology, trace fossils).

A variety of other small scale sedimentary features also occurs in shales, including mudcracks, load casts, flame structures, dewatering structures, graded rhythmites (Reineck and Singh, 1980), cross-lamination, loop structures (Cole and Picard, 1975), bioturbation (Wetzel and Uchmann, 1998), fossil concentrations and lags, all of

Shales, Figure 3 Migrating ripples of flocculated kaolinite in seawater, photographed through the bottom of a flume. Width of flume channel is 25 cm, flow direction indicated by red arrow. (From Schieber et al., 2007.) The ribbed "tails" behind the ripples are the eroded remains of foreset laminae.

which carry information about conditions of sedimentation. Among the more subtle sedimentary features are clay-filled mud cracks, brecciation due to desiccation, and sands or conglomerates that consist entirely of shale particles (Schieber, 1985). The latter can, for example, form as a result of soil erosion (pedogenic particles; Nanson et al., 1986; Rust and Nanson, 1989), erosion of cracked mud crusts, and submarine scouring of mud substrates by strong currents.

Biologic agents may produce microbial laminae and protection of mud surfaces from erosion (e.g., Schieber, 1986; O'Brien, 1990), or may manifest themselves as bioturbation and via destruction of primary fabrics (Wetzel and Uchmann, 1998). Infaunal activity that took place early in depositional history, when the muds had a high water content, may be exceedingly subtle and hard to detect after compaction (Schieber, 2003). In many instances of bioturbation sufficient proportions of primary features survive and can still be interpreted in terms of depositional processes. Careful examination of bioturbation features can provide additional information about substrate firmness, event deposits (escape traces), and rates of deposition. Fecal pellets and pelletal fabrics are another by-product of organic activity, and they are probably more abundant in mudstones and shales than commonly recognized (Pryor, 1975; Potter et al., 1980; Cuomo and Rhoads, 1987). Best seen in thin section, pellets typically differ from the shale matrix with respect to texture, color, and organic content. They range in size from 0.2–2 mm, are generally of elliptical outline, and

Shales, Figure 4 (a) Parallel-laminated black shale, New Albany Shale, Devonian, Indiana. Lighter laminae are silt enriched (the steeply inclined and slightly curved lines are saw marks). (b) A sample from the same core interval as seen in (a). In the center, we see inclined (to the left) truncated laminae, forming the outline of a compacted mud-dominated ripple. (c) Tracing of silt laminae visible in (b). Arrow marks an internal erosion surface. This is a fossil equivalent of migrating mud ripples observed in flume experiments. (From Schieber et al., 2007.)

flattened by compaction. If matrix and pellets are similar in composition and composed of particles of similar grain size, pellet identification can be challenging. Pellets of benthic versus planktonic organisms may be differentiated on the basis of composition (Cuomo and Bartholomew, 1991; Schieber, 1994).

Early diagenesis of shales

It is due to the abundance of endosedimentary microbes (Figure 1) that surficial muds are very active sediments from a geochemical perspective. Much of the initially buried organic material is remineralized in these water-rich sediments (80–90% initial water content), prompting the description of surficial muds as “fluidized bed reactors” (Aller, 1998). The microbial breakdown of buried organic matter requires terminal electron acceptors (oxidizing agents) and due to limitations by diffusion, overall abundance, and differences in energy yield for the various oxidation reactions, we observe a systematic exhaustion of available electron acceptors (e.g., oxygen, nitrate, iron (III), manganese (IV), sulfate, carbon dioxide) as we move downwards from the sediment-water interface. For these reasons closely comparable microbial decay profiles (Brett and Allison, 1998; Curtis et al., 2000) are observed in many marine sediments. For a detailed description of these microbial decay profiles, see Chapters *Sediment Diagenesis – Biologically Controlled* and *Pore Waters*.

A good number of diagenetic minerals, such as pyrite (Figure 5), are readily explained by these decay-reaction schemes (Brett and Allison, 1998; Curtis et al., 2000; Allison, 1988). For others that are not, associated pH shifts can nonetheless be instrumental for their precipitation. For example, early diagenetic silica (quartz) precipitation is not uncommon in shales (Figure 6). In Phanerozoic shales it is derived from the dissolution of biogenic opal (radiolarian, diatoms, sponge spicules) and fills pore spaces that range from tens of microns to as much as a millimeter in size (Figure 7). Quite frequently these pore fills (in situ quartz) are mistaken for detrital quartz (Schieber, 1996; Schieber et al., 2000).

If phosphorous is abundant in the initial mud, such as due to accumulation of phosphatic skeletal material, phosphatic concretions, ranging in size from less than a mm to more than 100 mm's, may form (Figure 8). An early diagenetic phosphate matrix seems to be an excellent medium for preserving minute details of soft tissues, such as in the Neoproterozoic Doushantuo Formation of China (Shen et al., 2000).

Due to the rapid and systematic expulsion of pore waters and decrease of porosity during compaction, early diagenetic minerals in shales are preferentially preserved. For this reason, shales contain a rich record of geochemical processes that relate closely to the chemistry of the overlying ocean waters and paleoceanographic conditions. When studied systematically, the authigenic component of shales holds the promise to capture a snapshot of seawater and/or porewater chemistry. With the necessary

Shales, Figure 5 Pyrite framboid from bottom muds of the Santa Barbara Basin. Note regular arrangement of euhedral subcrystals. The sediment layer in which this framboid occurs is only a few years old. Pyrite formation is associated with the activity of anaerobic bacteria that utilize seawater sulfate (SO_4) as an oxygen source and generate hydrogen sulfide as a byproduct. They are among the most common and familiar of early diagenetic mineral formations in shales.

age constraints, this may enable us to develop a much more detailed record of ocean geochemical changes than currently available.

Conclusion

Shales result from the complex interplay of a range of geologic variables and processes, and there are no easy answers and no “one size fits all” models. Although these rocks have an (undeserved) reputation for being drab, uniform, and uninteresting, the repay the investigative challenges they pose by being a rich storehouse of information about the geologic past. Sedimentological study includes recognition and tracing of facies changes, sedimentary features, shale fabrics, erosion surfaces and internal stratigraphy, as well as information that can be derived from interbedded non-shale lithologies. Paleontological studies may provide data on paleo-oxygenation, primary production, substrate conditions, paleocurrents, bathymetry, and paleosalinity (Schieber et al., 1998). Petrographic investigations provide the basic inventory of shale constituents, and may yield clues about provenance, compaction history, chemical conditions, sedimentary processes (via small scale sedimentary structures), and the origin and maturation of organic matter (Taylor et al., 1998). Chemical analysis of major and trace elements can provide information on provenance (Roser and Korsch, 1986), and a range of proxies for paleo-oxygenation (Jones and Manning, 1994). Organic geochemistry can furnish information on the source of organic matter, its dispersal,

Shales, Figure 6 SEM photomicrograph (backscatter image) of a pore space in the Devonian New Albany Shale (Indiana, USA), illustrating suboxic to anoxic diagenesis. Light gray mineral **an** is ankerite (Fe-Mg-Ca-carbonate) that initially grew in the interior of a *Tasmanites* cyst (dark black line), a locally reducing and anoxic microenvironment. Very early growth is indicated by the uncompacted *Tasmanites* wall and the overall circular growth of carbonate (**an** + **mc**) cement. Outside of the protected microenvironment of the cyst we see growth of manganoan calcite (**mc**, darker gray), indicating suboxic conditions in the sediment and oxygenated bottom waters. (From Calvert et al., 1996.) The carbonate cement is surrounded by fine crystalline quartz (**qu**), derived from dissolution of radiolarian opal. (From Schieber et al., 2000). The image suggests that pore waters were initially alkaline, allowing for precipitation of carbonates and dissolution of biogenic opal, and that this was followed by a lowering of pH that led to precipitation of quartz. This image illustrates the level of insight one can derive from careful petrographic study of early diagenetic cements.

and maturation (Engel and Macko, 1993). Certain organic molecules, such as photosynthetic pigments, may survive as “carbon skeletons” (biomarkers), and may identify the original source of diagenetically altered organic matter and potential indicators of water column anoxia (Brassell, 1992).

Fundamentally, shales do not give up their secrets easily. The tools are at hand, however, to extract a wide range of data from them and allow for multiple avenues of inquiry (Schieber et al., 1998). Interpretations that rely on just one perspective (e.g., petrography, fabric study, trace element geochemistry, or organic geochemistry) typically do not match conclusions derived from a different line of inquiry. Shales need to be investigated in a multidisciplinary way and at multiple scales because of the complex interplay of variables that produces them. Conclusions derived from microscopic features must be in agreement with insights coming out of basin scale studies, as well as with findings from all scales in between.

Shales, Figure 7 Authigenic quartz (chalcedony) in the late Devonian Chattanooga Shale (Kentucky, USA). (a) Photomicrograph in transmitted light. The clear/bright grains are chalcedonic infills of algal cysts (*Tasmanites*). (b) SEM image (backscatter) from the same specimen, showing more clearly the rounded-lobate outlines of the quartz grains and the enclosing cyst walls (black rim). For a detailed discussion of these features see Schieber (1996) and Schieber et al. (2000).

Shales, Figure 8 SEM photomicrograph (backscatter image) of an example of early diagenetic phosphate precipitation. The image shows what appears to be a colony of phosphate encrusted bacteria (Mid-Proterozoic Bijaigarh Shale, India).

Classification

Bacteria – Proteobacteria – Gammaproteobacteria – Alteromonadales – Shewanellaceae (Ivanova et al., 2004), fam. nov. – *Shewanella* (MacDonell and Colwell, 1985), gen. nov.

Definition

Assumed as one of the first metabolic processes of ancient microbial life (prior to oxygen, nitrate, and sulfate respiration), microbial iron reduction is still of particular interest

in recent geobiological systems. The efficiency of iron reducing microorganisms in utilizing structural or crystalline solid-phase Fe^{3+} oxide minerals as electron acceptors with respect to nutrient availability and pH is still matter of discussion; this type of metabolism, however, is an ubiquitous phenomenon, applied by a wide range of species throughout the Archaea and Bacteria (Weber et al., 2006 and references therein). Members of the family *Geobacteraceae* and the genus *Shewanella* are among the most significant and common studied organisms with regard to dissimilatory iron reduction and oxidation of organic matter in soils, sediments, and groundwater.

According to the surface complexation model (Dzombak and Morel, 1990), Warren and Ferris (1998) report on an equilibrium between ferric iron sorption and precipitation reactions on bacterial surfaces, emphasizing iron-reducing bacteria like *Shewanella* as highly reactive key players in pristine and contaminated waters (Pedersen and Albinsson, 1991).

Actually including 50 recognized species (List of prokaryotic names with standing in nomenclature: <http://www.bacterio.cict.fr/>), the genus *Shewanella* features Gram-negative, facultatively anaerobic, dissimilatory metal-reducing, rod-shaped organisms. Due to their highly diverse physiology, they inhabit a wide range of redox-stratified environments varying in nutrient composition, salinity, temperature, redox potential, and barometric pressure (marine and freshwater, surface, ground and deep waters, sediment, mud and soils), but also comprise symbiotic, epibiotic, and pathogenic species (Venkateswaran et al., 1998; Hau and Gralnick, 2007 and references therein). Under anaerobic conditions, most *Shewanella* species can produce hydrogen sulfide when grown on thiosulfate or polysulfide, and also can grow on lactate, pyruvate, formate, and on amino acids (Nealson and Scott, 2006 and references therein). For respiratory growth, they can use oxygen as well as a variety of different terminal electron acceptors, including nitrate, elemental sulfur, fumarate, dimethyl sulfoxide, and metals like Mn^{4+} , Fe^{3+} , As^{5+} , Cr^{6+} , Co^{3+} , Tc^{7+} , and U^{6+} (Nealson and Myers, 1992; Haas et al., 2001; Guha et al., 2003; Saltikov et al., 2003). As diffusion across the cell wall is not possible for metals in their solid form, metal-reducing *Shewanella* species specifically interact with the mineral surface to facilitate the electron transfer process by active cell adhesion in combination with a unique shuttle-system of proteins reaching from the cytoplasm to the outer membrane (Lower, 2001; Korenevsky and Beveridge, 2007; Fredrickson et al., 2008 and references therein).

Near-surface habitats may get limited in oxygen but not in minerals like iron oxyhydroxides (ferrihydrite, goethite, and hematite), in large part consisting of Fe^{3+} (Urrutia et al., 1998). In case of dissimilatory metal-reducing bacteria like *Shewanella*, Fe^{3+} is reductively dissolved during oxidation of carbon substrates, affecting processes like the biogeochemical cycle of iron and phosphorus, the oxidation of natural and anthropogenic carbon sources, and

SIDERITE

Volker Thiel
 University of Göttingen, Göttingen, Germany

Siderite is an iron carbonate mineral (FeCO_3 , 48% Fe) belonging to the calcite group (hexagonal crystal system). Magnesium and manganese may substitute for the iron. Siderite crystals are yellow to dark brown in color, rhombohedral in shape, and with curved and striated faces, and also occur in masses. Siderite is commonly found in bedded sedimentary iron ores, including banded iron formations (BIFs, see entry [Banded Iron Formations](#)), and in hydrothermal veins. It is also a common diagenetic mineral, forming at shallow burial depths in shales and sandstones where it tends to form concretions. The diagenetic formation of siderite strongly depends on the availability of Fe^{2+} ions in pore waters (see entry [Pore Waters](#)) and is thus a phenomenon of suboxic to anoxic environments (Berner, 1971). Diagenetic siderite precipitation has been linked to microbially mediated reactions, specifically to the release of ferrous (Fe^{2+}) iron due to dissimilatory iron reduction performed by Fe^{3+} -reducing prokaryotes (see entry [Fe\(III\)-Reducing Prokaryotes](#)) such as *Shewanella* (Roh et al., 2003; Hansel et al., 2003; see entry [Shewanella](#)). Microbially assisted siderite precipitation appears to preferentially occur in environments where the rate of bacterial iron reduction exceeds the rate of sulfate reduction performed by sulfate-reducing bacteria (Pye et al., 2006; see entry [Sulfate-Reducing Bacteria](#)). In sulfidogenic sediments, iron is largely precipitated as iron sulfide rather than as siderite (see entry [Iron Sulfide Formation](#)).

Definition

Siderophores are low molecular weight iron-specific organic ligands that are exuded by iron-limited organisms as part of a high-affinity iron acquisition strategy.

Introduction

Iron is a nutrient to almost all known organisms. Even though iron is the fourth most abundant element on earth, the acquisition of this nutrient poses a serious challenge to organisms in many natural environments. A particularly iron-depleted system is the photic zone of the marine water column (Kraemer et al., 2005). Here, soluble iron is removed by biological uptake and subsequent sinking of the biomass below the mixed zone. In ocean areas with particularly low iron concentrations relative to other nutrients in the photic zone, the primary productivity is limited by the low bioavailability of iron. This marine iron limitation may affect the global climate by limiting the efficiency of the marine carbon pump. However, even in soils that contain abundant iron-bearing mineral phases, iron acquisition poses a challenge to microbial and plant life. Indeed, the low solubility and dissolution rates of iron-bearing minerals in calcareous soils are responsible for large annual agricultural losses by plant iron limitation (iron chlorosis) (Kraemer et al., 2006).

The ability of organisms to scavenge iron from their surroundings is prerequisite to controlling intracellular iron concentrations within the physiologically required range (homeostasis). An efficient mechanism of iron

uptake involves the exudation of siderophores that are designed to bind iron(III) in the extracellular space with a sufficient affinity and specificity to ensure the formation of Fe(III)-siderophore complexes even in the presence of high concentrations of other competing cations and in the appropriate pH range. This high-affinity iron uptake strategy is used by bacteria (including cyanobacteria) in marine, freshwater, and terrestrial environments, by fungi and some plant species. Other iron acquisition mechanisms include the acidification of the environment, the reduction of Fe(III) coupled to Fe(II) uptake, or the secretion of other ligands (e.g., citrate) with lower affinity for iron. High-affinity iron uptake involving siderophores is generally the most efficient system in environments with extremely low iron availability.

Siderophore structure and properties

Siderophores are not defined by their chemical structure, but by their biological function. Several hundreds of distinct and structurally diverse siderophores are known. Siderophores are low molecular mass (<1,500 Dalton) organic ligands, typically chelating iron in hexadentate octahedral coordination, although siderophores with lower denticity are known. Iron is coordinated by hard ligating groups including hydroxamate, catecholate, carboxylate, and hydroxycarboxylate groups (Figure 1). The nature of the ligating groups and the optimization of the overall siderophore structure are responsible for their outstanding affinity for iron. For example, desferrioxamine B (DFO-B), a siderophore produced by the soil bacterium *Streptomyces pilosus* forms an iron complex with a 1:1 stability constant logK of 32.02 (Martell et al., 2001). The affinity of microbial siderophores for iron binding is much higher than for competing ions that are often found in high concentrations in the extracellular environment. For example, DFO-B does not, to measurable extent, coordinate with calcium in seawater or in pore water of calcareous soils (Kraemer et al., 2005, 2006). Most siderophores excreted by terrestrial organisms are highly water soluble, allowing the diffusion of siderophores toward insoluble iron sources. This is prerequisite to their function as an iron shuttle overcoming the necessity for the organisms to directly contact the iron source (Kraemer et al., 2006). However, amphiphilic siderophores possessing fatty acid tails have been isolated from cultures of distinct genera of marine bacteria (Martinez and Butler, 2007) and pathogenic bacteria. The inhibition of ligand diffusion away from individual bacteria by anchoring of amphiphilic siderophores in the plasma membrane seems to be advantageous in marine systems where bacterial abundances are low.

Graminaceous plant species, including agriculturally important crops, such as barley, wheat, and corn, are the only plant species known to possess a high-affinity iron uptake system. They exude a distinct class of iron-specific ligands with aminocarboxylate and hydroxycarboxylate functional groups, the so-called phytosiderophores or

METALS, ACQUISITION BY MARINE BACTERIA

Alison Butler, Vanessa V. Homann
 University of California, Santa Barbara, CA, USA

Definition

Oceanic bacteria produce siderophores to acquire iron. Given that the iron concentration in surface ocean water is very low, siderophores produced by marine bacteria are tailored to the physical and chemical constraints of the marine environment.

Introduction

Microbial iron uptake

Virtually, all bacteria require iron for growth. Bacteria growing under aerobic conditions utilize a variety of pathways to acquire iron, but under conditions of iron starvation, bacteria often produce siderophores (Crosa et al., 2004). Siderophores are low molecular weight, chelating compounds produced by bacteria to facilitate iron(III) uptake (Crosa et al., 2004; Kraemer et al., 2005; Butler, 2007). The Fe(III)-siderophore complex is recognized by a specific outer membrane protein receptor, which catalyzes the transport of the Fe(III)-siderophore complex across the outer membrane (Figure 1).

The study of marine microbial siderophores is relatively new (Butler and Martin, 2005), yet certain characteristic structural features have already begun to emerge: suites of amphiphilic siderophores and photoreactive Fe(III)-siderophores.

Marine Siderophores

Amphiphilic marine siderophores

One characteristic of marine siderophores is the predominance of suites of amphiphilic siderophores, comprised of a hydrophilic head group, which coordinates with Fe(III), and one of a series of hydrophobic fatty acid appendages, which confers amphiphilicity (Figure 2). Two types of suites of amphiphilic siderophores are produced by marine bacteria. The aquachelins, marinobactins, and amphibactins are amphiphilic peptidic siderophores produced by distinct genera of marine bacteria (Figure 2) (Martinez et al., 2000, 2003). The relative amphiphilicity of each of these siderophores is

Metals, Acquisition by Marine Bacteria, Figure 1 Siderophore-mediated iron uptake by a bacterium.

defined by both the number of amino acids in the peptide fraction, compared to the fatty acid chain length (e.g., C12–C18). The amphibactins with only four amino acids and relatively long C18 fatty acids are the most hydrophobic of the amphiphilic peptide siderophores. As a result, they remain cell associated and are extracted from the bacterial pellet during the isolation process (Martinez et al., 2003). In contrast, the marinobactins and aquachelins, with five and six amino acids in the head group and a predominance of the shorter fatty acids, are more hydrophilic and are thus isolated from the supernatant following centrifugation of the bacterial culture to pellet the cells (Martinez et al., 2000).

The synechobactins and ochrobactins (Figure 2) are different suites of amphiphilic siderophores, in which the head group is based on citric acid, as opposed to a peptide. The head group is thus smaller than in the peptidic amphiphilic siderophores. The fatty acids are also shorter than observed for the peptidic amphiphilic siderophores. Nevertheless, the ochrobactins are quite hydrophobic as a result of two fatty acid appendages; these siderophores remain associated with the bacterial pellet (Martin et al., 2006). The synechobactins, with

only one fatty acid appendage, partition between the culture supernatant and the bacterial pellet (Ito and Butler, 2005).

Photoreactive Fe(III)-siderophores

The other characteristic of marine siderophores is the predominance of α -hydroxycarboxylic acid moieties in the form of β -hydroxyaspartic acid or citric acid (Figures 2 and 3).

The Fe(III)-complex of an α -hydroxycarboxylic acid moiety is photoreactive in UV light, including natural sunlight, which is a condition experienced by the mixed layer of the upper 30–40 m of the ocean. Upon UV photolysis of the Fe(III)-siderophores containing citric acid, such as the ochrobactins (Martin et al., 2006), the synechobactins (Ito and Butler, 2005), the petrobactins (Bergeron et al., 2003; Hickford et al., 2004), and aerobactin (marine *Vibrio* sp. DS40M5) (Küpper et al., 2006; Haygood et al., 1993), citrate is oxidized to 3-ketoglutarate and Fe(III) is reduced to Fe(II). The resulting ligand photoproduct

retains the ability to coordinate Fe(III) with remarkably high stability constant as a result of the 3-ketoglutarate moiety and the remaining hydroxamic acid groups (Figure 4, for aerobactin (Küpper et al., 2006).

Other marine siderophores such as the aquachelins, the marinobactins, the alterobactins, and the pseudoalterobactins contain β -hydroxyaspartic acid as the α -hydroxycarboxylic acid group. UV photolysis of the Fe(III)-aquachelins results in ligand oxidation, specifically loss of β -hydroxyaspartic acid, as well as reduction of Fe(III) to Fe(II) (Barbeau et al., 2001). This peptide photoproduct retains the two hydroxamate groups and thus the ability to coordinate with Fe(III), although the conditional stability constant is somewhat reduced (Barbeau et al., 2001). Only catalytic amount of Fe(III) is required to effect the complete oxidation of the aquachelins in aerobic conditions, because the Fe(II) that is produced is oxidized back to Fe(III) and thus can coordinate with another apo aquachelin. The ferric complexes of the alterobactins A and B and the marinobactins are also photoreactive (Barbeau et al., 2003), although the

Metals, Acquisition by Marine Bacteria, Figure 3 Marine siderophores with α -hydroxycarboxylic acid groups. The aquachelins, marinobactins, ochrobactins, and synechobactins shown in Figure 2 also contain α -hydroxycarboxylic acid moiety. Alterobactins (Reid et al., 1993); pseudoalterobactins (Kano et al., 2003); aerobactin (Haygood et al., 1993); petrobactin (Bergeron et al., 2003); petrobactin-SO₃ (Hickford et al., 2004); vibrioferriin (Amin et al., 2007). The circled portion shows the α -hydroxyacid in citric acid.

structures of the oxidized ligands have not been completed yet. The ferric complexes of pseudoalterobactins A and B, which are chemically related to the alterobactins (Kano et al., 2003), would also be expected to be photoreactive.

Summary

The preponderance of suites of amphiphilic siderophores and of α -hydroxycarboxylic-acid-containing siderophores produced by marine bacteria suggests that these properties have evolved as common iron acquisition strategies for

marine bacteria, although details of the biological advantages conferred by these molecular properties are yet to be elucidated.

METEORITICS

Mark A. Sephton

Imperial College London, London, UK

Definition

Meteorites are fragments of extraterrestrial material that fall on the Earth's surface. Most meteorites are parts of asteroids propelled into Earth-crossing orbits by relatively recent collisions in the asteroid belt, initiated by the gravitational effects of Jupiter's orbit. Relatively small numbers of meteorites originate from larger objects such as the Moon and Mars. The Earth acquires 10^2 to 10^3 t of such material each day, but only 1% or less arrives in pieces large enough for identification and recovery (Dodd, 1981). The surface of the meteorite usually melts and emits a glowing tail and a trail of smoke, but the interior of the meteorite is unaffected by passage through the Earth's atmosphere and remains at the temperature of interplanetary space.

Collection of meteorites

“Falls” are meteorites that have been observed to fall and were subsequently collected; “finds” are meteorites that were not seen to fall. Before the 1970s, the total number of known meteorites amounted to less than 1,000 falls and 1,706 authenticated finds. Since then, it has been recognized that certain parts of the Earth's surface preserve and concentrate meteorites. To date, tens of thousands of meteorites have been collected from the Antarctic ice. Similar numbers of meteorite fragments have also been collected from hot deserts. Most recently, telescope and camera network surveys have produced meteorites with photographed fireballs allowing the calculation of their orbits and assignment to a particular source within the solar system (Bland et al., 2009).

Chondrites

About 85% of the meteorites observed to fall on the Earth are chondrites, conglomerate rocks with an overall elemental composition similar to the Sun, if the loss of the most volatile elements is ignored. When their near solar makeup is considered alongside radiometric ages of 4.56×10^9 years, it becomes clear that chondrites are rocks formed during, or shortly after, the birth of the Sun.

The record in chondrites

Their status as some of the earliest formed solids in the solar system combined with a lack of subsequent processing ensures that chondrites represent a valuable record of extraterrestrial environments. Contributing regions include interstellar space, the solar nebula and the asteroidal meteorite parent bodies.

SIDEROPHORES

Stephan M. Kraemer
University of Vienna, Vienna, Austria

Definition

Siderophores are low molecular weight iron-specific organic ligands that are exuded by iron-limited organisms as part of a high-affinity iron acquisition strategy.

Introduction

Iron is a nutrient to almost all known organisms. Even though iron is the fourth most abundant element on earth, the acquisition of this nutrient poses a serious challenge to organisms in many natural environments. A particularly iron-depleted system is the photic zone of the marine water column (Kraemer et al., 2005). Here, soluble iron is removed by biological uptake and subsequent sinking of the biomass below the mixed zone. In ocean areas with particularly low iron concentrations relative to other nutrients in the photic zone, the primary productivity is limited by the low bioavailability of iron. This marine iron limitation may affect the global climate by limiting the efficiency of the marine carbon pump. However, even in soils that contain abundant iron-bearing mineral phases, iron acquisition poses a challenge to microbial and plant life. Indeed, the low solubility and dissolution rates of iron-bearing minerals in calcareous soils are responsible for large annual agricultural losses by plant iron limitation (iron chlorosis) (Kraemer et al., 2006).

The ability of organisms to scavenge iron from their surroundings is prerequisite to controlling intracellular iron concentrations within the physiologically required range (homeostasis). An efficient mechanism of iron

uptake involves the exudation of siderophores that are designed to bind iron(III) in the extracellular space with a sufficient affinity and specificity to ensure the formation of Fe(III)-siderophore complexes even in the presence of high concentrations of other competing cations and in the appropriate pH range. This high-affinity iron uptake strategy is used by bacteria (including cyanobacteria) in marine, freshwater, and terrestrial environments, by fungi and some plant species. Other iron acquisition mechanisms include the acidification of the environment, the reduction of Fe(III) coupled to Fe(II) uptake, or the secretion of other ligands (e.g., citrate) with lower affinity for iron. High-affinity iron uptake involving siderophores is generally the most efficient system in environments with extremely low iron availability.

Siderophore structure and properties

Siderophores are not defined by their chemical structure, but by their biological function. Several hundreds of distinct and structurally diverse siderophores are known. Siderophores are low molecular mass (<1,500 Dalton) organic ligands, typically chelating iron in hexadentate octahedral coordination, although siderophores with lower denticity are known. Iron is coordinated by hard ligating groups including hydroxamate, catecholate, carboxylate, and hydroxycarboxylate groups (Figure 1). The nature of the ligating groups and the optimization of the overall siderophore structure are responsible for their outstanding affinity for iron. For example, desferrioxamine B (DFO-B), a siderophore produced by the soil bacterium *Streptomyces pilosus* forms an iron complex with a 1:1 stability constant logK of 32.02 (Martell et al., 2001). The affinity of microbial siderophores for iron binding is much higher than for competing ions that are often found in high concentrations in the extracellular environment. For example, DFO-B does not, to measurable extent, coordinate with calcium in seawater or in pore water of calcareous soils (Kraemer et al., 2005, 2006). Most siderophores excreted by terrestrial organisms are highly water soluble, allowing the diffusion of siderophores toward insoluble iron sources. This is prerequisite to their function as an iron shuttle overcoming the necessity for the organisms to directly contact the iron source (Kraemer et al., 2006). However, amphiphilic siderophores possessing fatty acid tails have been isolated from cultures of distinct genera of marine bacteria (Martinez and Butler, 2007) and pathogenic bacteria. The inhibition of ligand diffusion away from individual bacteria by anchoring of amphiphilic siderophores in the plasma membrane seems to be advantageous in marine systems where bacterial abundances are low.

Graminaceous plant species, including agriculturally important crops, such as barley, wheat, and corn, are the only plant species known to possess a high-affinity iron uptake system. They exude a distinct class of iron-specific ligands with aminocarboxylate and hydroxycarboxylate functional groups, the so-called phytosiderophores or

Siderophores, Figure 1 Chemical structures of the phytosiderophore mugineic acid and of microbial siderophores desferrioxamine B (DFO-B) and aerobactin.

mugineic acids (Takagi, 1976; Takagi et al., 1984) (Figure 1).

Uptake of Fe(III)-siderophore complexes

Gram-negative bacteria bind siderophore complexes by a receptor in the outer membrane followed by shuttling to the cytoplasmic membrane. Gram-positive bacteria have a receptor anchored to the cytoplasmic membrane. The complexes are then delivered to the cytoplasm by a transmembrane protein (ABC-transporter) (Andrews et al., 2003). Similarly, graminaceous plants possess a high-affinity uptake system specific for iron(III)-phytosiderophore complexes (Curie et al., 2001). Some microorganisms are known to be endowed with uptake systems for iron complexes of siderophores that are not produced by the same organism.

The intracellular release of iron from internalized siderophores is promoted by either hydrolysis of the siderophore or reduction of ferric iron to ferrous iron followed by competitive sequestration of the iron (Miethke and Marahiel, 2007). The biosynthesis and exudation of siderophores as well as the expression of their uptake systems are highly regulated as a response to iron limitation (Hantke, 2001).

Siderophore concentrations in natural environments

The exudation of siderophores is a costly strategy in terms of cellular nutrient and energy budgets, particularly in systems with low bacterial densities such as oligotrophic marine systems (Völker and Wolf-Gladrow, 1999).

Therefore, it is not surprising that observed siderophore concentration in the environment do not exceed iron concentrations required for efficient uptake. Powell et al. (1980) have estimated hydroxamate siderophore concentrations in soil solutions to be between 10 and 100 nM. Essen et al. (2006) found up to 2 and 12 nM of the hydroxamate siderophores ferrichrome and ferricrocin, respectively, in soil solutions of podzolic forest soils. However, the quantitative analysis of siderophores in natural waters remains challenging due to their structural diversity and low concentrations. For example, siderophores have not been detected unambiguously in ocean water even though iron complexes with conditional stability constants comparable to siderophore complexes in the nanomolar and subnanomolar concentration range have been observed by voltammetric techniques (Rue and Bruland, 1995). Römheld (1991) has estimated that phytosiderophore concentrations in the rhizosphere can reach local concentrations of up to 1 mM in the soil solution.

Sources of iron

The soluble iron concentrations in oxic soils or surface waters are limited by the solubility of iron oxides, iron hydroxides, or hydrous ferric oxide. In the neutral to slightly alkaline pH range corresponding to the pH of calcareous soil solutions and ocean water, their solubility reaches a minimum below 1 nM (Liu and Millero, 2002). The presence of iron complexing organic ligands can increase the iron solubility. Thus, iron complexes with low molecular weight organic ligands, fulvic and humic acids, as well as iron-bearing mineral phases (including

primary silicates and pedogenic iron oxides) are the most important iron sources for high-affinity uptake systems (Kraemer, 2004). Prerequisite for iron sequestration from these sources are the superior affinity of siderophores for iron compared to the stability of the iron complexes or minerals that serve as iron source and reasonably fast rates of the associated ligand exchange or dissolution reactions.

Siderophore promoted dissolution of iron oxides and iron-bearing silicates

Siderophores promote iron sequestration from iron oxides (Kraemer et al., 1999) and iron-bearing primary (e.g., hornblende [Liermann et al., 2000]) and secondary silicates [e.g., kaolinite (Rosenberg and Maurice, 2003)]. The effect of siderophores on iron dissolution rests on their ability to increase the solubility of iron and to accelerate dissolution rates. It has been shown that bacterial and plant siderophores promote iron oxide dissolution in the dark by a ligand-controlled dissolution mechanism, where the rate of dissolution is a linear function of the adsorbed siderophore concentration (Kraemer et al., 1999; Reichard et al., 2005). This mechanism is important in high-affinity iron acquisition by graminaceous plants. Considering the low concentrations of microbial siderophores observed in natural systems, their main function seems to be to increase solubility of iron oxides, generating thermodynamic driving force for other dissolution mechanisms (Cheah et al., 2003; Reichard et al., 2007).

Photochemistry of siderophore complexes

Soluble iron complexes of siderophores possessing α -hydroxycarboxylate ligating groups photolyze in seawater under irradiation by sunlight, resulting in oxidation of the ligand and formation of transient Fe(II) that is rapidly reoxidized (Barbeau, 2006). Both the Fe(II) and iron bound to the oxidized ligand are bioavailable to phototrophic phytoplankton that cannot take up Fe(III)-siderophore complexes. Moreover, siderophores promote photoreductive dissolution processes that tend to be faster than ligand-promoted dissolution reactions (Borer et al., 2005). These photochemical processes may be of key importance for algal and bacterial iron acquisition in marine systems.

Formation of siderophore complexes with other metals and their uptake

A prerequisite for the efficiency of the high-affinity iron uptake system is the ability of organisms to discriminate against uptake of other (potentially deleterious) metal ions. The selectivity of the uptake system is ensured by the high specificity of siderophores for iron binding relative to most cations in solution and by the specific recognition of iron(III)-siderophore complexes by receptors at the cell surfaces. However, some exceptions to the selectivity of iron binding and uptake are known. Siderophores have a high affinity for metal ions with an equal or higher charge to radius ratio than Fe(III). For example, the

siderophore DFO-B forms a Pu(IV) complex with a 1:1 stability constant that is orders of magnitude higher than the corresponding iron complex (Boukhalfa et al., 2007). Moreover, slow uptake of Pu(IV)-siderophore complexes by the high-affinity iron uptake system of *Microbacterium flavescens* has been observed (John et al., 2001). The formation of plutonium-siderophore complexes and their bacterial uptake illustrate that the selectivity for a metal ion other than iron does not necessarily imply that the metal ion is actively targeted by the high-affinity uptake system for the purpose of nutrition. Also, the siderophore DFO-B has a high selectivity for the trivalent manganese ion (Duckworth and Sposito, 2005). Manganese in this redox state is not commonly observed in the absence of the siderophores, but the shifted redox potential of the complex stabilizes Mn(III) under conditions that are found in natural systems. In order to appreciate the effect that siderophores may have on the geochemistry of metal ions other than iron, it is important to keep in mind the extremely low siderophore concentrations measured in natural systems (vide supra).

Uptake of phytosiderophore complexes of Fe(II), Ni(II), Zn(II), Cu(II), Mn(II), and Cd(II) by maize (*Zea mays*) has been observed (Schaaf et al., 2004), and it has been controversially discussed if their uptake by the high-affinity iron uptake system is regulated or fortuitous. A high-affinity uptake system also seems to promote the uptake of molybdenum and vanadium by the nitrogen fixing soil bacterium *Azotobacter vinelandii* (Bellenger et al., 2008). Methanotrophic bacteria use a high-affinity uptake system for copper acquisition involving the exudation of Cu(I) specific organic ligands, the so-called chalcophores. Chalcophores have a distinctly different architecture compared to siderophores involving nitrogen and sulfur as ligands (Kim et al., 2004).

Conclusions

The key role of siderophores in marine and terrestrial biological iron acquisition is well established. However, a thorough and quantitative understanding of their effect on processes involved in, e.g., global carbon cycling or crop production requires a better understanding of how siderophores influence the availability and distribution of iron among prokaryotic and eukaryotic organisms in complex ecosystems. New observations of siderophore photochemistry, their amphiphilic properties and their mineral surface chemistry as well as observations of iron speciation in natural systems are important steps in this direction. Furthermore, recent work has shown that nutrient acquisition involving the exudation of ion-specific ligands is not unique to high-affinity iron acquisition. Discoveries of other similar nutrient acquisition systems may reshape our thinking about the effect of trace metal biogeochemistry on the microbial ecology of oligotrophic natural systems and vice versa. Finally, the unique properties of siderophores and other ion-specific biogenic ligands continue to inspire technical applications in fields such as pollutant remediation or biomedicine.

SILICOFLAGELLATES

Silicoflagellates are planktonic, microscopic algae with siliceous skeletons, characterized by their simple geometries and remarkable variability. Taxonomically, they belong to different classes of the Stramenopiles and possess complex plastids derived from secondary endosymbiosis (see entry [Symbiosis](#)). Silicoflagellate skeletons may have considerable potential as environmental indicators and are common in fossil deposits, dating back to the middle Cretaceous (ca. 120 Ma), with species diversity reaching a peak in the Miocene (ca. 23–25 Ma). Today, only a single genus *Dictyocha* with approximately five recognized species exists. For more details, please refer to entry ["Algae \(Eukaryotic\)"](#).

Synonyms

Silica sinter; Siliceous sinter

Definition

Sinter: A sedimentary rock primarily composed of silica that is precipitated from hot waters at the vents of high-temperature (high-enthalpy) hot springs and geysers, and from cooled waters on their surrounding discharge aprons.

Geyserite. A dense, banded or laminated variety of sinter that forms at and near the vents of geysers and some high-temperature springs.

Some banded and laminated types of nonmarine carbonates (calcite or aragonite), including spring travertines and speleothems, have also been termed “sinter” or “calc-sinter.” We suggest that the geological term “sinter” should be restricted to *siliceous* deposits precipitated from silica-rich waters discharged at hot springs and geysers.

Introduction

Sinters are deposits of silica precipitated by hot waters discharged at the vents of hot springs and geysers. Most sinters are precipitated as noncrystalline opal-A, but they change to quartz during diagenesis. They form almost exclusively in high-enthalpy geothermal fields where the underground reservoir temperatures exceed $\sim 220^{\circ}\text{C}$, and so are most common in volcanic and tectonically active regions. Most geysers discharge from vents lined with sinter. Weed (1889) was among the first to discuss the role of microorganisms in the formation of sinter. After his pioneering work, very little scientific study was done on these rocks until Allen (1934) described sinters at Yellowstone. Walter (1976) undertook petrographic study of sinters, including stromatolitic types. Rimstidt and Cole (1983) made one of the first detailed studies of the chemistry of sinter formation. Krumbein and Werner (1983), followed later by Cady and Farmer (1996) and Jones and Renaut (1996), described, illustrated, and interpreted silicified microbes in recent sinters. Since then, interest in these unusual rocks has increased significantly, and more than 140 studies of sinters have been published during the past decade. The possible role of bacteria in silica precipitation has been a focus of much interest. Many filamentous and coccoid microbes preserved in recent sinters resemble the microfossils found in Precambrian quartzose cherts.

Morphology of sinter deposits

Most sinter is gray to white in color, but the addition of trace elements can produce vividly colored deposits such as the orange sinters found around the edge of Champagne Pool, Waiotapu, New Zealand (Jones and Renaut, 2003, Figure 2b). The main types of sinter deposit are *mounds*, which form around the vents of many geysers, *pool-rim dams* that precipitate around the margins of hot-spring pools, and various types of *terraces* and *platforms* that form downslope from the vent(s) on the spring or geyser discharge apron. Sinter mounds (Figure 1a) develop where aqueous silica precipitates from fluids that overflow the margins of a geyser vent or small-diameter point-sourced spring, or from silica that precipitates from air-borne spray. Sinter mounds can be columnar, domal, or broadly conical with slopes that range from nearly vertical to low angled ($<10^{\circ}$). Mounds vary from decimeters to meters in height and up to several meters in basal diameter. Many factors control mound morphology including the

original shape and dimensions of the vent, the volume and type of discharge (i.e., geyser versus hot spring activity), the original slope, climate (e.g., predominant wind direction), and water chemistry (e.g., silica concentration). Mound morphology can vary with time as the sinter deposits build up or the pattern or volume of discharge changes.

Pool-rim dams (Figure 1b) form where silica precipitates around the edges of hot-spring pools and some (fountain-type) geysers. The discharged water either flows across the lowest parts of the dam or escapes through erosional notches. Nested concentric pool-rim dams, each with different elevations, may form when mean water level in the pool changes because of external (e.g., hydrostatic) controls.

Water discharged from hot springs either flows across the land surface forming a “discharge apron” or it may flow directly into the local (nonthermal) drainage system. Outflow waters that mix with river or lake waters can be diluted below saturation with respect to amorphous silica, so that any sinter deposits are restricted to the vent area. If undiluted, however, the thermal outflow will cool progressively downslope leading to more silica precipitation. Sinter terraces (Figure 1c–f) commonly form where silica-laden waters flow across slopes, precipitating sheets of silica, as they cool and (or) evaporate. Each terrace is composed of a rimstone dam and pool. In scale, they range from miniterraces a few centimeters across, to large terraces tens of meters across, with dams several meters high. Some terrace pools temporarily pond water, but much of the outflow crosses terrace surfaces as largely unconfined sheets a few millimeters deep. Where several active vents lie near each other, their terraces may merge to form extensive flat sinter platforms.

Silica precipitated from hot waters also forms many small features including oncoids and pisoids (geyser eggs), which typically accrete in shallow pools near geyser vents; silica stalactites, which grow below overhanging terraces; and many small-scale ornate forms of geyserite on proximal sinter terraces (Figure 1e and g). Stromatolites develop locally in ponds or spring pools in the outflow system, usually where water temperature is $<70^{\circ}\text{C}$.

The thickest, most extensive sinter deposits form in neutral to alkaline waters (pH 7–9.5). The sinters that form in acid to neutral waters (pH 2–7) tend to be thin (millimeter to decimeter rather than meter thick). They lack some of the complex ornamentation of sinters forming in more alkaline fluids (Figure 1h), but commonly show spicular and bladed morphologies, and tend to be glassier in appearance than sinters forming in alkaline waters.

Microorganisms and sinter

Petrographic and scanning electron microscope (SEM) studies of sinter commonly reveal abundant silicified remains of microbes including coccoid and filamentous bacteria, eukaryotic algae, diatoms, fungi, and

(g) Ornate geyserite deposits near a geyser vent at El Tatio geothermal field, Chile. (h) Thin platy sinter precipitated by acidic waters on the southern shore of Hot Pools Lake, Rotokawa, New Zealand. The sinter, which was probably precipitated by capillary processes, shows desiccation(?) cracks partly filled by silica cements.

extracellular polymeric substances (EPS) (Figure 2). Near spring vents and on many terraces where waters have cooled to $<70^{\circ}\text{C}$, microbial mats commonly cover the substrate and can become encrusted and (or) replaced by opaline silica. Bunches of current-aligned, partially silicified, filamentous cyanobacteria (stringers) are present in some channels. If hydrothermal discharge is ephemeral and the terrace surfaces dry out periodically, microbial mats may be absent. However, biofilms, some thinly

(millimeter thick) coated by opaline silica, and endoliths may still be present either at or just below the terrace surface, including sites very close to active vents.

Microbial fossils are preserved in most settings from vent to distal discharge apron. In waters $>75^{\circ}\text{C}$, nonphotosynthetic prokaryotes, including heterotrophic and chemolithotrophic bacteria and archaea, are present, although their silicified remains are often difficult to identify. Cyanobacteria and photosynthetic bacteria

commonly inhabit waters from ~ 65 – 75°C (e.g., *Synechococcus*, *Chloroflexus*), with a wider range of cyanobacteria at temperatures $<65^\circ\text{C}$ (e.g., *Phormidium*, *Spirulina*, *Anabaena*, *Oscillatoria*, *Calothrix*, and others). Eukaryotic algae colonize substrates at temperatures $<60^\circ\text{C}$ and diatoms at $<45^\circ\text{C}$. Diatoms, fungi, and *Cyanidium* spp. are often the dominant fossil microbes in sinters precipitated from acidic fluids. Macrophytes, including grasses, wetland species, and trees and their root systems, may also be submerged by hot spring fluids and encrusted or replaced by amorphous silica.

Mineralogy and petrology

Most sinter is precipitated as noncrystalline opaline silica (opal-A: $\text{SiO}_2 \cdot n\text{H}_2\text{O}$) that can contain up to ~ 20 wt.% H_2O ; less commonly, chalcedony is a primary mineral. Although sinters precipitated from neutral and alkaline fluids are commonly monomineralic, silica precipitated from acidic fluids is commonly accompanied by kaolinite, ferric oxyhydroxides, alunite, jarosite, pyrite, and gypsum.

Sinters exhibit a wide range of textures and fabrics. Geyserites tend to be laminated, columnar, or stromatolitic, and generally have low primary porosity. Sintors that form distally from the vent are more diverse and include bedded and laminated facies that form on terraces, commonly with in situ silicified microbial mats, fenestral porosity, and intraclasts reworked from silicified mats upslope. Early cementation by opaline silica commonly masks the original fabrics, producing apparently massive sinter, but slight differences in the water content of the precipitated opal-A can help differentiate primary textures and cements (Jones and Renaut, 2004).

During diagenesis, the opal-A transforms to opal-CT, moganite, and ultimately quartz. The opal-A to opal-CT transformation can be rapid (Lynne et al., 2006; Jones and Renaut, 2007) and proceeds mainly by dissolution–reprecipitation reactions.

Origin of sinter

Silica solubility increases with increasing temperature, pH, and pressure, and can be influenced by other factors such as the presence of certain ions (e.g., Al, Fe) and salinity. Most silica precipitation at hot springs has been attributed to the cooling of thermal fluids that have equilibrated with respect to quartz, chalcedony, or volcanic glass at depth, and then rise rapidly to the surface, emerging as hot water supersaturated with respect to amorphous silica (White et al., 1956; Rimstidt and Cole, 1983; Fournier, 1985).

Much of the dissolved silica is present in its monomeric form (H_4SiO_4). As saturation increases, silica polymerization occurs through reactions that involve linear, cyclic, and three-dimensional forms of polymeric silica (Iler, 1979). In strongly supersaturated fluids, including some spring pools, nuclei grow by Ostwald ripening into nanospheres and microspheres (10 nm–1 μm) and may

form colloidal particle suspensions (sols). Continued growth of spheres can destabilize the sols and fine sediment settles from suspension. If the pH falls or the electrolyte concentrations increase (e.g., by evaporation), suspended particles may flocculate, forming aggregates that eventually sink to the substrate. In both cases, the silica sediment then undergoes cementation to form sinter. At sites of evaporative concentration, microspheres may coagulate to form gels. In contrast, at relatively low levels of supersaturation, dissolved silica precipitates mainly by heterogeneous nucleation upon existing substrates or suspended particles.

Evaporative concentration can induce silica precipitation at hot springs in semiarid and arid regions (e.g., Kenya Rift), although evaporation is usually less effective than cooling in humid environments. However, evaporation is an important mechanism on subaerial sites of periodic wetting including outflow terraces between geyser eruptions and sites receiving airborne spray. Seasonal freezing of geothermal outflow can also induce opal-A precipitation and agglomeration by “cryogelling,” which concentrates silica in residual fluid as ice is formed (Channing and Butler, 2007).

The pH and salinity also affect amorphous silica solubility. Nucleation and polymerization are inhibited in acidic waters because monomeric silica is slow to deprotonate (Fournier, 1985; Mountain et al., 2003), which explains the thin sinter development around acid hot springs. At $\text{pH} > \sim 9$, silica dissociates into other species, increasing the solubility. A rapid decrease in pH of a highly alkaline, silica-saturated thermal fluid might induce amorphous silica to precipitate on contact with neutral lake waters or groundwaters or if the fluid is acidified by microbes.

The waters that flow from most geysers and many hot springs in the geothermal fields of Iceland, New Zealand, Kamchatka, Chile, and Yellowstone, are strongly supersaturated with respect to amorphous silica so should precipitate silica abiotically upon rapid atmospheric cooling. Physical processes control the gross morphology of most sinter deposits, whereas chemical processes control the silica precipitation mechanisms. There has been much debate about whether or not microbes mediate silica precipitation and silicification, particularly in waters where homogeneous nucleation does not occur. Microbes can provide reactive surface ligands that adsorb aqueous silica from solution, and should therefore promote heterogeneous nucleation by reducing activation energy barriers. Three main mechanisms have been proposed: hydrogen bonding, cation bridging by metals (especially Fe), and electrostatic interactions (Phoenix et al., 2003; Lalonde et al., 2005; Konhauser, 2007, pp. 156–160). Although consensus has not yet been attained, most recent field studies (e.g., Jones et al., 2004) and laboratory experiments (e.g., Fein et al., 2002; Yee et al., 2003) suggest that the role of microbes in silica precipitation is largely incidental, especially in strongly supersaturated fluids. At lower levels of supersaturation, they may provide organic

substrates for heterogeneous nucleation. Bacteria (including cyanobacteria), however, control microfabric development in many types of sinter, over a wide range of scales and fluid temperatures (Jones and Renaut, 2003).

Fossil sinter

Fossil sinters, also termed paleosinters, are increasingly being recognized in the geological record. They commonly form “caprocks” to some epithermal mineral deposits (e.g., Guido et al., 2002) but are rarely a target of study. Two exceptions are the early Devonian Rhynie and Windyfield cherts of Aberdeenshire, Scotland (Trewin, 1994), and the Devonian–Carboniferous sinters of the Drummond Basin, Australia (Walter et al., 1996).

Conclusions

By mass, sinters are trivial compared to most sedimentary rocks, but their rarity belies their importance. Hot spring sinters form in one of the few environments where silica precipitation and silicification processes can be studied at the Earth’s surface, another environment being highly alkaline lakes. Consequently, they will remain important in studying how microbes and plants are silicified, both in modern environments and the geological record.

SKELETON

Biologically, a skeleton is a hard or rigid framework that could provide protection and support in many types of organisms. Most of skeletons are mineralized, but some may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, not including hydroskeletons. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites. Endoskeletons are internal hard parts (typical of many vertebrates). Most of endoskeletons are generally surrounded by skin and musculature. See entry "[Animal Skeletons, Advent](#)" for further reading.

SMALL SHELLY FOSSILS

Small shelly fossils (SSF, also "Small Shelly Fauna") is a non-taxonomic term, first used by Matthews and Missarzhevsky in the title of their review paper in 1975, to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites. See entries "[Animal Skeletons, Advent](#)" and "[Critical Intervals in Earth History](#)" for further reading.

SNOWBALL EARTH

Paul F. Hoffman
Harvard University, Cambridge, MA, USA

Synonyms

Cryochron; Global glaciation; Hard snowball; Ice-albedo catastrophe; Snowball (in geology); White Earth

Definition

Snowball Earth is a climate in which the oceans and most land areas are permanently covered by glacial ice. As less sunlight is absorbed by ice than by water or land, a critical area of ice will cause surface temperatures to fall below freezing everywhere, resulting in a snowball Earth. This arguably occurred near the beginning and end of the Proterozoic eon. Snowball Earths self-destruct after millions of years due to the buildup of atmospheric carbon dioxide of volcanic and metamorphic origin, which could not be converted into organic matter or limestone. Biological evolution is a postulated cause and consequence of snowball episodes.

History of the concept

Sedimentary deposits of glacial origin were first described from the late Proterozoic (Neoproterozoic) of Scotland in 1871 and from the early Proterozoic (Paleoproterozoic) of Canada in 1907. By 1940, it was apparent that the Neoproterozoic glaciation(s) had been more extreme than those of the Pleistocene and at least equal in severity to the late Paleozoic glaciations of Gondwanaland. In the 1960s, the occurrence of glacial deposits within thick successions of nearly pure carbonate strata suggested that Neoproterozoic ice sheets had entered what were normally the warmest parts of the globe. This was confirmed in the 1980–1990s by reliable paleomagnetic data showing that ice sheets had reached the ocean close to the paleoequator in the Neoproterozoic of Australia and Paleoproterozoic of South Africa (Evans, 2003). Moreover, evidence of marine geochemical anomalies concurrent with glaciation came increasingly to light in the form of sedimentary Fe_2O_3 and MnO_2 ore deposits, large excursions in stable carbon and sulfur isotopic compositions of minerals precipitated from seawater, and distinctive post-glacial "cap" carbonate sediments that rest directly on the terminal glacial deposit at all latitudes (Hoffman and Schrag, 2002). Neoproterozoic glacial deposits are now known from 22 different paleocontinents and microcontinents, and Paleoproterozoic deposits from 6.

The fraction of incoming solar radiation absorbed by ocean water under cloudless skies is 0.9, but for continuous ice it is only 0.4–0.6 and as low as 0.1 if the ice is covered by fresh snow. In the 1950–1960s, calculations by meteorologists of zonal average surface temperatures at different latitudes, assuming radiative energy balance and incorporating crude parameterizations of the radiative effects of clouds, meridional heat transport, and positive feedbacks due to the reflectivity (albedo) of ice, suggested that a lowering of solar luminosity by a few percent would result in a globe-encircling glaciation, or "white" Earth (North, 1990). If the luminosity is incrementally lowered, polar ice caps expand until their edges reach a critical latitude, beyond which ice advances rapidly to the equator without any additional luminosity reduction, or even with increased luminosity. This is due to runaway ice-albedo feedback – more ice reflects more radiation, creating more ice. (The same calculations indicated that a small increase in radiative forcing, due to anthropogenic CO_2 emissions for example, could cause a sudden loss of polar sea ice at a critical $p\text{CO}_2$ threshold.) These sensational findings greatly stimulated the nascent field of climate modeling, but proponents were puzzled how a "white" Earth disaster had been averted given that solar luminosity has increased by 25–30% over geological time (the so-called faint young Sun paradox). They assumed (incorrectly, as it turned out) that such an occurrence would extinguish all life – deep-sea chemoautotrophs and polar extremophiles were then unknown – and would be permanent because of the very large increase (~25%) in radiative forcing required to overwhelm a "white" Earth's high albedo.

As meteorologists assumed that a “white” Earth never occurred, they did not think to consult geologists, who remained oblivious to their findings.

In 1981, planetary scientists (Walker et al., 1981) proposed that Earth’s climate is modulated within the habitable range by a negative climate feedback resulting from the temperature-dependence of silicate-rock weathering. In the geochemical cycle of carbon, this is the means by which atmospheric CO_2 (dissolved in rainwater) is converted into bicarbonate ion (HCO_3^-), which dissolved in runoff makes its way to the ocean, where it is removed from circulation by the burial of carbonate sediments and organic matter. The feedback operates on a geological timescale ($\sim 10^6$ year) and causes the climate system to slowly seek whatever atmospheric CO_2 level, and hence climate, that is needed to balance the rate of CO_2 removal by silicate weathering with the rate of CO_2 emitted by volcanoes and metamorphic reactions. Walker et al. (1981) suggested that this feedback had prevented a “white” Earth disaster but noted that if one did occur, the consequent reduction of weathering rates would lead to an inexorable increase in atmospheric CO_2 as plate tectonics and therefore of CO_2 emissions would continue unabated. With the present emission rate and no CO_2 consumption, $p\text{CO}_2$ would increase to ~ 1.0 bar after 20 Myr. At some critical $p\text{CO}_2$, the “white” Earth would self-destruct violently due to ice-albedo and other positive feedbacks, leaving a transient aftermath in which high $p\text{CO}_2$, low surface albedo, and the recently deglaciated surface would conspire to cause intense weathering, exponentially lowering atmospheric $p\text{CO}_2$. The hysteresis loop in CO_2 versus planetary albedo means that a “white” Earth would be long-lived (10^6 – 10^7 year) but swift to melt (10^3 – 10^4 year), giving rise to a “greenhouse” transient (10^5 – 10^6 year). These are geologically testable predictions. But as the paleomagnetic evidence for global glaciation was not secure until 1986 (Evans, 2000), consideration of a self-reversing “white” Earth as a model for the geological record was delayed.

It was the paleomagnetist Joseph L. Kirschvink who first applied these concepts to low-latitude Neoproterozoic (Kirschvink, 1992) and Paleoproterozoic (Kirschvink et al., 2000) glaciations. He related the synglacial Fe_2O_3 and MnO_2 ore deposits to ocean stagnation and anoxia, caused by ice cover, which allowed the metals to be transported widely in solution in reduced form, and be precipitated upon deglaciation when the ocean was again ventilated. He predicted the global occurrence of sediments recording the abrupt climate switch at glacial terminations, later recognized as cap carbonates (Hoffman et al., 1998b). He speculated that an unusual preponderance of low-latitude continents (a situation that never occurred after 500 Ma) raised the planetary albedo to the critical threshold. He named the phenomenon “snowball” Earth as that is how the globe would appear from outer space. The name tacitly recognizes that the hydrological cycle, although greatly diminished on the cold solid

surface, would still be weakly maintained by sublimation and precipitation, not of snowflakes, but of tiny hexagonal snow prisms due to the global average surface temperature of around -50°C (Furukawa and Wettlaufer, 2007).

Number, age, and duration of snowballs

At least three snowball episodes are inferred from the geological record, two in the Cryogenian Period (~ 850 – 635 Ma) of the Neoproterozoic era (1,000–551 Ma), and one or more in the first half of the Paleoproterozoic era (2,500–1,600 Ma). The 1.5×10^9 -year interval between older and younger snowballs is curiously devoid of glacial deposits. The timing of the youngest snowball is the best constrained and of the oldest the most poorly known. This is primarily a function of differences in their respective areas of preservation. Termination of the youngest snowball occurred in 635 Ma, coincident with the boundary between the Cryogenian and Ediacaran Periods (Knoll et al., 2006b). The age is based on ultra-precise (0.5 Myr uncertainty) U-Pb geochronology of primary zircons from volcanic ash-falls in Namibia and South China (Halverson, 2006). Sections in other regions are correlated with these based on synde glacial “cap” carbonates (see below), which are uniquely distinctive in many areas. The onset of the snowball is loosely constrained. It is younger than 654.5 ± 3.8 Ma in South China, based on ion-microprobe U-Pb geochronology (Zhang et al., 2008). The maximum duration of this snowball was 23 Myr.

The timing of the older Cryogenian snowball is weakly constrained (Halverson, 2006): its onset is younger than 726 ± 1 Ma in Oman and 725 ± 10 Ma in South China, and its termination occurred before 667 ± 5 Ma in the western USA. In Oman, strata within the glacial succession are no older than 713 ± 1 Ma. Interregional correlation of glacial strata is more uncertain than for the younger Cryogenian glaciation. There is fragmentary evidence for an earlier Cryogenian glaciation of presumed regional scale ~ 750 Ma in central and southern Africa, while a mid-Ediacaran glaciation of short duration occurred in eastern Newfoundland, Canada, at 582 Ma (Knoll et al., 2006b), with possible correlatives in western and northern Europe, central Asia, Western Australia, and southwestern Brazil.

Paleoproterozoic glacial deposits in the western Transvaal, South Africa, are interfingering with volcanic lavas erupted near sea level at $11 \pm 5^\circ$ paleolatitude (Evans et al., 1997) approximately 2.22 Ga (10^9 year before present) (Kopp et al., 2005). The duration of the low-latitude glaciation is unknown. Three distinct glaciations occurred between 2.45 and 2.22 Ga in the Huronian succession of Ontario, Canada, and correlative glacial deposits occurred in Wyoming (USA), Quebec (Canada) and possibly Finland (Ojakangas, 1988). The paleolatitudes of these deposits being unknown, they are assumed to represent regional-scale glaciations.

Paleogeographic reconstructions and paleoclimatic indicators in bounding strata

At the time of the Cryogenian snowballs, many continents were in low paleolatitudes and few if any were near the poles (Trindade and Macouin, 2007). This is consistent with cold climates because a preponderance of low-latitude continents maximizes the rate of atmospheric CO₂ consumption by silicate weathering. It was also a time of fragmentation and dispersal of the long-lived (1.0–0.8 Ga) supercontinent Rodinia (Li et al., 2008). Continental fragmentation also enhances silicate weathering by bringing land closer to the source of moisture. Cryogenian paleogeography contrasted with that of the late Paleozoic ice ages, when a supercontinent (Pangea) had just formed and the glaciated lands (Gondwanaland) lay in a polar region. Little is known of early Paleoproterozoic paleogeography, but there are suggestions that they accompanied the fragmentation of land-masses consolidated in the late Archean eon (2.7–2.5 Ga).

Cryogenian glacial deposits are found within thick successions of shallow-water carbonate rocks in Namibia, California, Arctic Alaska, and southern Mongolia (Halverson et al., 2005). This is paradoxical because non-skeletal carbonates form preferentially in the warmest parts of the surface ocean on account of their “reverse” solubility. Throughout Earth history, thick carbonate successions formed only at latitudes less than 35° (Ziegler et al., 1984; Opdyke and Wilkinson, 1990). Their range did not change between warmer and colder climates because their distribution depends on the relative not the absolute temperature. Thus the meridional temperature gradient has never been reversed due to high orbital obliquity (Evans, 2006), as has been proposed to account for low-latitude glaciation (Schmidt and Williams, 1995). If glaciers reached the ocean in the warmest areas of the world, then the colder areas must also have been frozen.

Sedimentology of the glaciogenic deposits

The sedimentology and inferentially the depositional processes of Proterozoic and Phanerozoic glacial deposits are quite similar (Boulton and Deynoux, 1981; Hambrey and Harland, 1981). Those more interested in the rocks themselves than in their distribution have a hard time believing that Proterozoic ice ages were different in character. They range from terrestrial lodgement, moraine and outwash (sandur) complexes to glaciomarine grounding-line wedges and fans, and proglacial suspension fallout with or without sediment gravity flows and ice-rafted debris (Kellerhals and Matter, 2003).

Shaped and striated clasts, subglacial pavements with grooves and chatter marks, and stratigraphic relations suggestive of ice streams (currents of fast-flowing ice within an ice sheet) all attest to dynamic glacial action (Hoffman, 2005). At first it was thought that dynamic ice sheets were inconsistent with a snowball because the frozen ocean could not resupply them with snow. However, climate models suggest that net sublimation of subtropical

sea-ice would supply ice sheets with up to centimeters of ice-equivalent annually, meaning that ice sheets would thicken sufficiently to generate dynamic ice streams within a few 10⁵ year, a fraction of the estimated snowballs duration (Donnadieu et al., 2003; Pollard and Kasting, 2004). Accordingly, the evidence for dynamic ice sheets is not incompatible with a frozen ocean.

On the Otavi carbonate platform of Namibia, the younger Cryogenian glaciation left a continuous grounding-line prism situated 500–1,000 m vertically below the rim of the platform (Hoffman, 2005). This is quite unlike any Quaternary ice grounding line in polar seas, which typically switched between the inner and outer shelf. The grounding-line prism in Namibia is directly overlain by a synde glacial “cap” dolostone (see below) deposited above prevailing wave-base, the only shallow-water deposit at such depth on the slope (Hoffman et al., 2007). This indicates glacioeustatic changes of >500 m, consistent with an average ice-sheet thickness of >1.1 km over all continents. An important implication of this finding is that shelves and platforms were above sea level during most of the glacial interval, and any glaciomarine deposits found there could only have been deposited when the deglaciation was well-advanced. The nature of such deposits has often been cited as inconsistent with snowball conditions (e.g., wave action, phototrophism, ice-rafting, etc.). This is true; by the time they were deposited, the snowball no longer existed.

Associated marine geochemical anomalies

Fe₂O₃- and MnO₂-ore formations

During the Fe-ore exploration boom following World War II, it was learned that the only “banded iron-formations” (BIF) younger than 1.9 Ga are intimately and exclusive associated with Cryogenian glacial deposits (Klein, 2005). Extensive ore-grade deposits of Fe₂O₃ (±MnO₂) were found in SE Australia, SW Brazil, NW Canada, and Namibia. The Australian and Canadian deposits are in the older Cryogenian assemblage, the Brazilian ones are in the younger(?) Cryogenian assemblage, and the Namibian deposits are in both(?). As only reduced Fe(II) is soluble in seawater, Martin (1964) attributed “this peculiar combination of sediments” to “oxygen deficiency in stagnating bottom waters caused by an ice cover.” Canfield and Raiswell (1999) pointed out that decreased continental runoff during a snowball would lower the influx of sulfate to the ocean, which after bacterial sulfate reduction, removes dissolved Fe(II) from seawater in the form of FeS₂ (pyrite). Lowering the influx of sulfate therefore raises the concentration of Fe(II). The large sea-level fall associated with a snowball also raises the Fe:S flux ratio in mid-ocean ridge hydrothermal vent fluids on account of the drop in hydrostatic pressure (Kump and Seyfried, 2005).

Kirschvink (1992) suggested that the dissolved Fe(II) was oxidized to insoluble Fe(III) at snowball terminations, consistent with the stratigraphic position of the Australian

BIF near the top of the glacial sequence. Elsewhere, BIF occurs as sporadic lenses within glaciomarine sequences and Fe oxidation may have been caused by discharging of oxic subglacial meltwater along the grounding lines of ice shelves.

The 2.22-Ga Makganyene glaciation in South Africa ended with outpourings of mafic lava and the deposition of major Fe- and Mn-ore deposits. The latter are the world's largest and imply the presence of abundant molecular O_2 (not required for Fe oxidation) ~ 0.22 Gyr after atmospheric O_2 first rose above 10^{-6} PAL (present atmospheric level) according to mass-independent sulfur isotope fractionation data (Farquhar et al., 2000). The youngest pre-Cryogenian BIFs are limited to collisional (foredeep) basins (1.89 Ga) around the Superior craton of North America, unrelated to glaciation.

"Cap" carbonates

"Cap" carbonates are highly continuous, meter- to decameter-thick layers of relatively pure carbonate lying sharply without significant hiatus on top of the last glacial deposits of a snowball (Hoffman and Schrag, 2002; Shields, 2005). They typically extend far beyond the actual glacial deposits at the same stratigraphic horizon.

The best developed cap carbonates are those associated with the youngest snowball deglaciation in 635 Ma: they are global in extent and sedimentologically unique in the entire stratigraphic column (Allen and Hoffman, 2005; Shields, 2005; Hoffman et al., 2007). They begin with a layer of pale gray, often pinkish, micro- and macropeloidal dolostone ($Ca_{0.5}Mg_{0.5}CO_3$). Its global average thickness is ~ 20 m and it was laid down diachronously, mainly above storm wave-base, during glacioeustatic flooding of continental margins and inland seas (Hoffman et al., 2007). Assuming that strong positive climate feedbacks (e.g., ice albedo, ice elevation, CO_2 degassing, gas-hydrate destabilization) drove snowball deglaciation on timescales < 10 kyr, cap dolostone accumulation rates were > 2 mm year $^{-1}$.

The dolostone contains anomalous sedimentary features such as giant wave ripples (Allen and Hoffman, 2005) and stromatolite biostromes containing strictly vertical tubes of internal sediment with meniscus-like laminae (Corsetti and Grotzinger, 2005). The top of the dolostone layer in some areas is marked by a continuous crust of primary seafloor $BaSO_4$ (barite) cement in the form of digitate rosettes (pseudostromatolites) with internal growth lamellae (Hoffman and Schrag, 2002). The barite crust and other redox-sensitive geochemical (Hurtgen et al., 2006) and biomolecular (Elie et al., 2007) proxies indicate that an oxic-anoxic interface within the water column intersected the seafloor at this horizon. In subsiding areas, the dolostone is overlain by deeper water shales or limestones, locally with layer-upon-layer of seafloor cements in the form of macroscopic crystal fans originally composed of aragonite, the orthorhombic polymorph of $CaCO_3$ (James et al., 2001). In

non-subsiding areas, the dolostone layer ends at a subaerial exposure surface heavily disrupted by products of phreatic and vadose diagenesis (Hoffman and Schrag, 2002; Shields et al., 2007).

The nature and extent of the 635-Ma cap carbonate indicates an ocean in which the mixed layer and thermocline waters were highly oversaturated with respect to $(CaMg)CO_3$ and $CaCO_3$ respectively. Sources of alkalinity responsible for the anomalous saturation state include the weathering of carbonate and silicate rock powder and debris exposed by deglaciation (Higgins and Schrag, 2003; Anderson, 2007), anaerobic oxidation of CH_4 released by melting of permafrost in organic-rich shelf sediments glacioeustatically exposed during the snowball (Kennedy et al., 2001; Jiang et al., 2003), and anaerobic respiration at depth of organic matter produced in surface waters newly exposed to sunlight (Font et al., 2006). It was suggested (Kennedy, 1996; Ridgwell et al., 2003) that the 635-Ma cap carbonate can be explained by analogy with the "coral reef hypothesis" of Quaternary glacial-interglacial cycles (Berger, 1982), in which alkalinity builds up in deep waters during glacial stages because of the loss of shelf area, where carbonate is normally sequestered without passage through corrosive deep waters. This mechanism presupposes continued carbonate production in open ocean surface waters during the glaciation, for which evidence is lacking.

The cap carbonate ending the older Cryogenian snowball is different in character but comparable in thickness to the one just described, as well as in its sharp basal contact. Lithologically, it is usually a dark, fetid, limestone or dolostone, locally rhodochrosite ($MnCO_3$), deposited below storm wave-base. Former aragonite seafloor cements are prominent in some areas, notably in eastern Brazil (Vieira et al., 2007). In Namibia, there are hundreds of meters of continuous sublittoral microbialaminates with distinctive roll-up structures (Hoffman et al., 1998a). Missing altogether is the transgressive cap dolostone characteristic of the 635-Ma deglaciation. Carbonate production evidently did not begin until after deglaciation was complete, suggesting a weaker alkalinity flux into the ocean or a lower saturation state when the deglaciation began.

Cap carbonates a few centimeters to decimeters thick occur locally above the mid-Ediacaran (582 Ma) and early Cryogenian (~ 750 Ma) glacial deposits, believed to represent regional-scale glaciations.

In the Paleoproterozoic, the middle Huronian glacial formation has an impure cap limestone up to 17 m thick, the only carbonate unit in a terrigenous clastic succession up to 12 km thick (Bekker et al., 2005). The low-latitude Makganyene glaciation (~ 2.22 Ga) in South Africa has a possible cap carbonate (Mooidrai Formation) known only from subsurface bore holes (Kirschvink et al., 2000).

Post-glacial isotopic anomalies

Cap carbonates are typically depleted in ^{13}C (i.e., $\delta^{13}C < 0.0\text{‰}$ PDB) and detailed studies of expanded

sections of the 635-Ma cap carbonate in different areas show large negative isotopic excursions (Halverson et al., 2005). Excursions are deviations over time in a positive (higher $\delta^{13}\text{C}$) or negative direction, followed by a return to previous values. The excursion begins $\sim 0\text{‰}$ at the base of the oldest (deepest) cap dolostone, descends through the cap dolostone to a low of -6‰ in the basal limestones (after a $\sim 1.5\text{‰}$ step-function across the dolostone–limestone transition), and then rises slowly back to $\sim 0\text{‰}$. Its stratigraphic thickness depends on the sedimentation rate: on the Otavi platform, Namibia, it is ~ 400 m thick but only ~ 50 m thick on the deeper slope sections (formerly the ice grounding-line zone). The origin of the excursion is disputed (e.g., Kennedy et al., 2001; Higgins and Schrag, 2003).

The same cap carbonate hosts negative excursions in $\delta^{11}\text{B}$, interpreted as an expression of greatly elevated $p\text{CO}_2$ (Kasemann et al., 2005), and $\delta^{34}\text{S}$ of carbonate-associated sulfate (CAS), interpreted as oxidized sulfidic snowball waters (Hurtgen et al., 2006). The negative $\delta^{34}\text{S}$ excursion is followed by a positive one with lows and highs of 15 and 45‰, respectively. The positive values (the highest in Earth history) are attributed by a rapid increase in isotopic fractionation between sedimentary sulfate and pyrite, without a compensatory decline in the fractional burial rate of pyrite (Halverson and Hurtgen, 2007).

The older Cryogenian cap carbonate preserves only the rising leg of the post-glacial isotopic excursions, reflecting stratigraphic truncation (non-deposition) during glacioeustatic flooding. Surface waters became strongly enriched ($\delta^{13}\text{C} > 4\text{‰}$) again soon after carbonate production resumed (Yoshioka et al., 2003). Paired negative and positive $\delta^{34}\text{S}_{\text{CAS}}$ excursions resemble those above the younger snowball but data are fewer (Hurtgen et al., 2002).

The two known Paleoproterozoic cap carbonates are also depleted in ^{13}C (Kirschvink et al., 2000; Bekker et al., 2005), but lack local isotopic context as they occur in clastic-dominated successions. A major positive $\delta^{13}\text{C}$ excursion (Lomagundi excursion) appears to begin before age-equivalents of the Makganyene glaciation in North America (Bekker et al., 2006).

Pre-glacial isotopic anomalies

Both Cryogenian snowballs were preceded by long ($>10^7$ year) intervals of consistent isotopic enrichment ($\delta^{13}\text{C} \geq 5\text{‰}$ PDB), followed by Myr-long excursions to much depleted values ($\delta^{13}\text{C} \leq -5\text{‰}$), variably truncated by subglacial erosion. There is no accompanying $\delta^{34}\text{S}$ excursion. The excursions largely predate sea-level falls due to ice-sheet growth. Schrag et al. (2002) suggest that the prolonged isotopic enrichment reflects high fractional organic burial due to rapid sediment burial and expanded suboxic zones on preponderantly low-latitude continental margins. They propose that this situation ultimately led to a slow rise in atmospheric CH_4 due to methanogenesis in

organic-rich sediments. The rise in CH_4 is held responsible for the negative $\delta^{13}\text{C}$ excursion (Halverson et al., 2002). Silicate weathering feedback would lower $p\text{CO}_2$ in response to a slow rise in CH_4 , causing the climate to become more unstable because of its greater sensitivity to CH_4 concentration and the absence of buffering of its concentration by the ocean. Greater stochastic variability in a cold climate increases the risk of exceeding the critical threshold for runaway ice-albedo feedback. Unusual stromatolite and oolite development during the pre-glacial negative $\delta^{13}\text{C}$ excursions could reflect a rise in pH caused by the proposed lowering of $p\text{CO}_2$. The methane substitution model (Schrag et al., 2002) may not be viable, however, because it depends on an unrealistic residence time for CH_4 in the Cryogenian atmosphere of $>10^5$ year. Unless their timing around 1 Myr before the onsets of both Cryogenian snowballs is a coincidence, or merely wrong, the negative $\delta^{13}\text{C}$ excursions should have some bearing on snowball causation.

Climate modeling

Climate models are used to simulate the conditions under which a snowball could initiate, develop over time, and deglaciate. Ideally, an atmospheric general circulation model (AGCM) would be coupled to a dynamic ocean model, a dynamic ice-sheet model, a dynamic sea-ice model, and an interactive model of the geochemical cycle of carbon. In reality, this is computationally unattainable in the foreseeable future. To begin with, full-blown AGCMs are typically run to equilibrium over ~ 100 model years, which are ~ 4 orders of magnitude less than the adjustment time for the geochemical carbon cycle. Therefore, atmospheric CO_2 concentrations are either prescribed at various levels, providing “snapshots” under arbitrary conditions, or else a greatly simplified AGCM must be employed.

Snowball climate models must be adjusted for ambient Proterozoic conditions. Solar luminosity was $\sim 7\%$ lower than present in the Cryogenian and 16–20% lower at 2.22 Ga (Crowley and North, 1991). The Earth’s rotation rate was $\sim 10\%$ higher in the Cryogenian (Williams, 2000) and faster by an unknown amount in the Paleoproterozoic. And Proterozoic continents had higher albedos in the absence of forest cover. These factors all tend to lower the global mean surface temperature and would have resulted in compensatory higher levels of atmospheric CO_2 (Walker et al., 1981).

Modeling suggests that while snowball initiation is resisted by ocean dynamics (Bendtsen, 2002; Poulsen and Jacob, 2004), it is assisted by atmospheric Hadley convection (Bendtsen, 2002), flowage of ice-shelf ice (Goodman and Pierrehumbert, 2003), and wind-driven sea ice (Lewis et al., 2007). Both the thickness of tropical sea ice and the CO_2 level required for deglaciation are highly sensitive to the prescribed ice albedos (Warren et al., 2002; Pollard and Kasting, 2005; Lewis et al., 2006; Le Hir et al., 2007). The role of clouds is complex

and is a major source of uncertainty in the models (Pierrehumbert, 2005).

Theories of causation

In addition to the methane substitution model described above, a number of other astronomical, oceanographic, geodynamic, and biological theories have been proposed to account for low latitude glaciation. Astronomical theories include solar variations (Harland, 1964), large orbital obliquity (Williams, 1975), ice-ring collapses (Sheldon, 1984), impact ejecta (Bendtsen and Bjerrum, 2002; Fawcett and Boslough, 2002), and passage through giant molecular clouds (Pavlov et al., 2005). The large obliquity hypothesis is the most testable and contested of these models (Néron de Surgy and Laskar, 1997; Williams et al., 1998; Pais et al., 1999; Maloof et al., 2002; Levrard and Laskar, 2003). Oceanographic theories include enhanced carbonate burial (Roberts, 1971), intermittent ocean stagnation (Kaufman et al., 1993; Grotzinger and Knoll, 1995), glacioeustatic hypsometry change (Ridgwell et al., 2003), and enhanced organic burial (Kaufman et al., 1997). Geodynamic theories involve continental distribution (Kirschvink, 1992; Schrag et al., 2002), supercontinent breakup (Donnadieu et al., 2004), flood-basalt weathering (Goddéris et al., 2003), and true polar wander (Li et al., 2004). Biological theories include the evolution of biocatalyzed weathering (Carver and Vardavas, 1994), methane destruction (Pavlov et al., 2000, 2003; Catling et al., 2001; Claire et al., 2006), methane substitution (Halverson et al., 2002; Schrag et al., 2002), and the evolution of oxygenic photosynthesis (Kopp et al., 2005). As the ultimate cause of the Quaternary ice ages remains obscure, it is not surprising that the “why” question for Proterozoic snowballs is undecided. Different snowball may have had different causes, but whatever their cause, it was an uncommon occurrence.

Snowballs and the history of oxygenation

There is increasing evidence for stepwise increases in environmental oxygenation near the beginning and end of the Proterozoic eon, roughly contemporaneous with the inferred snowballs. This is the empirical motivation for causative theories involving the oxidative destruction of reduced “greenhouse” gases (Pavlov et al., 2000, 2003; Catling et al., 2001; Kopp et al., 2005; Claire et al., 2006). To make a climatic impact, changes in oxygenation must occur rapidly ($<10^6$ year), or else silicate weathering feedback will cause compensatory adjustments in $p\text{CO}_2$, largely nullifying the effect on radiative forcing.

Mass-independent sulfur isotope fractionation data indicate that atmospheric O_2 concentrations remained below 10^{-6} PAL (present atmospheric level) until ~ 2.45 Ga, close to the first Huronian glaciation and ~ 230 Myr before the Makganyene snowball. The same data suggest the possibility that O_2 remained very low

(but $>10^{-6}$ PAL) during the intervening interval. However, deposition of the succeeding Kalahari MnO_2 -ore formation required at least transient O_2 concentrations >5 orders of magnitude higher than this, possibly caused by a photosynthetic “bloom” and resultant organic burial in the snowball aftermath (Kirschvink et al., 2000) or by H_2O_2 (hydrogen peroxide) released by the melting of snowball ice (Liang et al., 2006).

There is increasing evidence that the deep oceans remained anoxic, but sulfidic not ferrous, during most of the 1.5 Gyr ice-age gap between the Makganyene and the Cryogenian snowballs (Scott et al., 2008). Mass-dependent S-isotope data imply that seawater sulfate concentrations remained low (<4 mM) between the Cryogenian snowballs (Hurtgen et al., 2002), but rose rapidly to near modern (29 mM) levels in the early Ediacaran (Halverson and Hurtgen, 2007). This rise in marine sulfate, presumably caused by increased atmospheric $p\text{O}_2$, appears to follow rather than lead the end-Cryogenian snowball. However, the response time between oxygenation and methane destruction is much shorter than between oxygenation and growth of the marine sulfate reservoir, so an increase in oxygenation to trigger the snowball is not ruled out by these data.

Implications for evolutionary biology

Eukaryotic survival

The younger Phanerozoic glaciations had little impact on the course of biological evolution as measured by rates of origination or extinction of taxa: only the Hirnantian (latest Ordovician) glaciation ~ 445 Ma was accompanied by major mass extinctions. Snowballs, however, presented qualitatively different challenges to existing biota, if they actually occurred. For millions of years, mean annual surface temperatures at the equator would have resembled those of Antarctica today. Areas where sunlight and liquid water coexisted were severely limited, hot springs and zones of perpetual crack development where mobile sea ice encountered fixed rocky substrates. With permanent ice cover, seawater would be starved of oxygen, becoming anoxic due to sinks for oxygen in the ocean. It would become progressively more acidic due to submarine volcanic CO_2 emissions and air–sea gas exchange through cracks at rates lower than the oxygen consumption rate. The geochemical response of the ocean to these afflictions is complex, but seawater pH would probably be lowered by 2.0–2.5 pH units (Le Hir et al., 2008). Deep-sea vent biota would be adversely affected by reduced Eh and pH gradients between hydrothermal fluids and seawater. With low overall productivity, nutrient levels would be high, except for fixed nitrogen due to denitrification. Upon deglaciation, a “bloom” of primary producers would occur, contingent upon nitrate availability. The bloom might be delayed because meltwater injection and surface warming would combine to produce an unusually stable density stratification (Shields, 2005), temporarily suppressing nutrient-upwelling from depth. A 635-Ma

cap carbonate in southwestern Brazil preserves a molecular record of this bloom in the form of an unusual assemblage of biomarkers pointing to a low-diversity eukaryotic flora dominated by red algae and a prokaryotic biota rich in green sulfur bacteria (Elie et al., 2007). The latter imply anoxic waters at the base of the photic zone and the former are consistent with low levels of illumination as exists, for example, in a turbid water column.

No biologist doubts that prokaryotic life, bacteria and archaea, could survive a snowball cryochron and its aftermath. Some do question if eukaryotic algae could survive (but see Vincent et al., 2004). As several extant clades of eukaryotic algae evolved before the Cryogenian, their survival causes some to doubt the existence of snowballs (Knoll, 2003). This is the attraction of more benign but less physically plausible climate states like “slushball” Earth, wherein continents are glaciated at all latitudes (satisfying geological observations) but half of the ocean remains ice-free (Peltier et al., 2004). However, the slushball solution provides no satisfactory explanation for synglacial Fe- and Mn-ore deposits (Klein, 2005), for cap carbonates (Pollard and Kasting, 2005) or for the multimillion-year duration of Cryogenian glaciations inferred from stratigraphic subsidence analysis (Hoffman and Schrag, 2002).

The only fossil record that is sufficiently continuous to bear directly on the evolutionary impact of snowballs is the record of organic-walled, acid-resistant microfossils representing a variety of eukaryotic algae, protists, and possibly fungi (Knoll et al., 2006a). Their Proterozoic record is characterized by extremely low rates of turnover (extinctions and originations) of taxa, roughly 100× slower than in the Ediacaran and Phanerozoic, following the last snowball (Peterson et al., 2005). The sparser macrofossil record is also consistent with slow turnover. Taxonomic diversity drops precipitously during the interval that includes the Cryogenian snowballs (Knoll et al., 2006a), with the inevitable result that it is little studied by palynologists. There have been no systematic studies to determine if the interval of very low diversity actually begins at the first Cryogenian snowball. The microfossil record effectively starts only after the Paleoproterozoic snowball (Knoll, 2003).

Evolutionary innovation

Since the mid-twentieth century, geologists have speculated that Neoproterozoic glaciation and its aftermath was somehow responsible for the advent of multicellular animals, the first fossils of which were known to occur not too far above the glacial deposits in many areas (Harland and Rudwick, 1964). (Note this was not the advent of multicellularity *per se*, which occurred earlier in algae (Knoll, 2003).) In the 1990s, with improvements of radiometric dating, this connection appeared less likely: the canonical Cambrian “explosion” in diversity of animal taxa with hard parts did not occur until ~530–520 Ma and

the oldest macrofossils arguably attributable to metazoans, the enigmatic Ediacara biota, appear ~580 Ma. This is >100 Myr and 55 Myr, respectively, after the last snowball ended in 635 Ma. In contrast, molecular divergence in modern animals, calibrated by known branching points in the geological record (so-called molecular “clocks”), gave estimates of animal origins much older than the Cryogenian snowballs.

However, recent evidence from microfossils and molecular fossils appears to put the connection back in play once again. In South China, remarkable cysts enclosing metazoan diapause eggs and embryos extend down to strata deposited within ~3 Myr (632 Ma) of the last snowball termination in the same area (Yin et al., 2007). In Oman, molecular fossils (24-isopropylcholesterol) believed to be diagnostic of sponges are found down to and even within correlative glacial deposits (Love et al., 2009). In addition, new molecular “clock” analyses place the origin of eumetazoa more in line with the new fossil evidence (Peterson and Butterfield, 2005), while the molecular signature of animal radiation indicates a geologically instantaneous event (Rokas et al., 2005).

How might the environmental stress of a snowball and its aftermath have contributed to revolutionary biological innovation? One idea involves the dual role of heat-shock protein 90 (HSP90) in suppressing the expression of mutant signal transduction proteins and in promoting the proper folding of stress-damaged proteins (Baker, 2006). Under extreme temperatures, HSP90 is diverted from the former role in favor of the latter, allowing accumulated cryptic mutations to be phenotypically expressed and therefore subject to natural selection. Another possibility is that spatial isolation of biological refugia in a snowball favored the evolution of altruism, a basic requirement for intercellular cooperation, by promoting kin selection and eliminating non-altruistic invaders (Boyle et al., 2007).

The evolutionary impact of the Paleoproterozoic snowball(s) is even more conjectural as there is no detailed fossil evidence for synchronicity. Nevertheless, it has been suggested that horizontal gene transfer between taxa at levels higher than at the species level was triggered by environmental catastrophes, and that these gene exchanges were responsible for such macroevolutionary innovations of possible Paleoproterozoic age as thermophilic and photosynthetic bacteria, and the eukaryotic cell (Hartman, 2002). Molecular fossil evidence for an Archean (pre-snowball) origin for oxygenic photosynthesis and for eukaryotes has been presented (Brocks et al., 1999; Summons et al., 1999); however, more recent studies suggest that the “biomarkers” in question are less phylogenetically diagnostic than earlier believed (Fischer et al., 2005; Kopp et al., 2005; Rashby et al., 2007). Finally, the surprising finding that the highest 18S rRNA gene diversity in extant protists and the richest in ancestral lineages occurs in Arctic communities (Stoeck et al., 2007) suggests the possibility that snowballs figured prominently in their evolution.

Conclusion

Important new evidence for extreme atmospheric carbon dioxide concentrations during and after the Marinoan snowball Earth has recently been obtained from mass-independent oxygen isotope ratios in sulfate minerals (Bao et al., 2008, 2009).

Summary

Virtually all continents were covered by large ice sheets during two discrete intervals of the Cryogenian Period (between 725 and 635 Ma). The multimillion-year duration of the glacial intervals, the deposition of syn-glacial Fe₂O₃ and MnO₂ sedimentary ores in different areas and of post-glacial “cap” carbonates at all latitudes support the hypothesis that the world ocean was also ice-covered. These episodes represent a climate state unknown on Earth since 635 Ma, or in the 1.5 Gyr before 725 Ma. Climate models indicate that the pan-glacial climates, popularly known as snowball Earth, were the result of runaway ice-albedo feedback, and that they were reversed by infra-red radiative forcing due to the accumulation of atmospheric CO₂ of volcanic-metamorphic origin, which could not be removed because of the absence of liquid precipitation when surface temperatures were below freezing everywhere. New microfossil and molecular biomarker evidence opens up the possibility that the origin of multicellular animals was related to these climate shocks. Evidence for glaciation at low paleolatitudes around 2.22 Ga, also associated with sedimentary Fe and Mn ores, suggests the existence of snowball states possibly related to the initial rise of atmospheric O₂.

Definition

The term “soda lake” designates a class of lakes with waters showing an excess of the total alkalinity ($TA \cong [HCO_3^-] + 2[CO_3^{2-}]$, i.e., the sum of the charges of the bicarbonate ion plus carbonate ion) over the charges of the alkaline earth ions magnesium and calcium:

When such water is evaporated, the high $[CO_3^{2-}]$ concentrations will cause a rise in pH and eventually, Na carbonates precipitate. These are soda (or natron, $Na_2CO_3 \cdot 10H_2O$, monoclinic), trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, monoclinic), and thermonatrite ($Na_2CO_3 \cdot H_2O$, orthorhombic). They are commercially used in the glass-, textile-, paint-, soap- and metal-industry, mined worldwide (Garret, 1992).

Occurrence

Soda lakes occur worldwide, albeit in very specific zones: they seem to be associated with active tectonic and volcanic zones (Figure 1). Most of the famous soda lakes occur in East Africa along the East African rift (e.g., Kraml and Bull, 1998/1999). Here, the succession of soda lakes left deeply buried soda deposits that also serve as the source of natro-carbonatite lavas (Ol Doinyo Lengai Stratovolcano, Tanzania). Another well-known group of alkaline lakes, some fossil such as Searles Lake, occur in the western USA. Less well known are lakes on the Altiplano, or in Australia, Afghanistan, Turkey, and other places around the world. So far no comprehensive list of soda lakes has apparently been compiled.

Setting

However, there seem to be two different types of lakes that acquire soda chemistry: most of the larger lakes are depressions in endorheic regions closed toward exorheic runoff by tectonic movements or by volcanic dams. The ratio between the tributary area and lake surface area is large. The largest soda lake on the Earth is Lake Van (Van Gölü) in eastern Anatolia (e.g., Kempe et al., 1991). Table 1 gives its morphometric data; it is (because Lake Aral dried up) by volume the third largest closed basin lake on Earth. Lake Van occupies the former headwaters of the Euphrates before it was dammed by an eruption of the Nemrut volcano.

The other class of soda lakes occur in volcanic craters or calderas. They typically do not have any surface tributaries and their ratio between recharge area and lake surface area is small. We have discovered the alkaline nature of several crater lakes, including Satonda Crater,

Soda Lakes, Table 1 Lake Van morphometric data

Total basin area	16,096 km ²
Total tributary area	12,574 km ²
Lake surface	3,522 km ²
Lake volume	576 km ³
Lake maximum depth	451 m
Annual water exchange	3.78 km ³
Altitude of lake level	1,648 m a.s.l.

Source: Kempe and Kazmierczak (2003); Compiled from Reimer (1995)

Indonesia (Kempe and Kazmierczak, 1993), Niuafo'ou Caldera Lake, Tonga (Kazmierczak and Kempe, 2006), and Kauhako Crater Lake, Molokai, Hawaii (unpublished data and Donachie et al., 2004). Other soda lakes occupy the Empakai Crater in Kenya, the crater in Pantelleria, and possibly a score of other craters that have not been investigated as yet. Even Santorini, Greece, must have had an alkaline crater lake for some period prior to the famous Minoan eruption that blew out the stromatolites of that lake.

Chemistry

Soda lakes can reach pH in excess of 10.5 and alkalinities of >150 meq/l. Some of the most alkaline water bodies are Lake Magadi (Eugster, 1986) in Kenya and Mono Lake in California (e.g., Bischoff et al., 1993). Lake Van has a pH of 9.7 and an alkalinity of 151 meq/l (Kempe et al., 1991; Reimer et al., 2009). These are examples of highly alkaline lakes. But there are soda lakes “in the making,” i.e., lakes that obey the basic condition of $TA > (Mg + Ca)$ but have not acquired higher salinities. One of them is the crater lake of the Nemrut Volcano itself that has dammed Lake Van. In Table 2 the water of Lake Van is compared with that of the Nemrut Lake.

The Table lists the main parameters that are used to characterize natural waters, all in all the two lakes are not very different in their respective surface and bottom samples, i.e., they are relatively well mixed. First of all the conductivity gives a rough measure of the amount of total salts dissolved, which is in seawater about 35 g/l, in Lake Van it is about 22 g/l, and in Nemrut Lake only about 440 mg/l, i.e., Nemrut Lake is what would be classified as a “fresh water” lake. But this is only one of the criteria: when calculating the soda lake criterion

(i.e., $TA/(Mg + Ca)$) we find 16.65 and 16.85 for Lake Van (0 and 440 m, respectively), 3.11 and 3.18 for Lake Nemrut (10 and 150 m, respectively) and 0.018 for seawater. This ratio tells us that Lake Van is a typical soda lake with >16 times as much alkalinity as alkaline earth ions, but that also Lake Nemrut is a soda lake with >3 times higher alkalinity than alkaline earth ions; whereas seawater has much more Mg and Ca than dissolved carbonates (i.e., >54 times). We also see that the chemical

composition of both lakes do not differ much with depth, apart from the pH in Nemrut Crater that drops considerably. Lake Van has a very high pH as expected from its high alkalinity. But Nemrut crater lake has – at the surface – the same slightly alkaline pH as seawater, not identifying it (yet) as a soda lake. When from these data (and temperature not given here) the CO_2 pressure of the water (PCO_2) is calculated (using PHREEQE; Parkhurst et al., 1990) and compared to the PCO_2 of the atmosphere of

Soda Lakes, Table 2 Chemical composition of Lake Van, the largest contemporary soda lake, compared to Nemrut Crater Lake, a “soda lake in the making” and to modern seawater

Lake/Depth	pH	PCO_2 ppmv	Alkal. meq/l	Cl meq/l	SO_4 meq/l	Na meq/l	Mg meq/ l	Ca meq/l	Cond $\mu S/cm$	SI_{Cc}	SI_{Ara}	SI_{Dol}

Cc = calcite; Ara = aragonite; Dol = dolomite

380 ppm, then we find that the crater lake has a much higher PCO_2 than the other samples, indicating that it receives volcanic CO_2 from subsurface springs, while Lake Van does not.

PHREEQE also allows for calculating the state of saturation of water with respect to minerals. The saturation index (SI) is defined as the logarithm of the ion activity product divided by the solubility constant of a given mineral (here, for calcite as an example):

$$SI_{\text{calcite}} = \log([Ca^{2+}] * [CO_3^{2-}] / K_{\text{calcite}}).$$

The SI yields negative values if water is undersaturated, zero if saturated, and positive values if supersaturated. The results (Table 2) show that all samples, with the exception of the deep Nemrut sample, are oversaturated with respect to calcite, aragonite, and dolomite. But when the deep Nemrut sample is numerically degassed, it will also show high carbonate supersaturation (last line in Table 2). The main difference between Lake Van and seawater is that the carbonate supersaturation (which is >10 times its saturation) of Lake Van allows for in situ precipitation of aragonite, while in seawater, even though supersaturated, no spontaneous precipitation occurs. Rather, the supersaturation of seawater is kept low by the multitude of enzymatically biomineralizing organisms that are generally absent in soda lakes due to the high alkalinity.

Soda lake microbialites

Those of the mature soda lakes that reach high supersaturation values (i.e., above $\approx SI\ 0.8$, Kempe and Kazmierczak, 1990) produce cyanobacterial microbialites. Table 3 lists

a few of them for which sufficient geochemical data are available to calculate saturation. The water analysis available for Andros Island originally do not show supersaturation, but the permineralizing cyanobacterial mats grow in ephemeral very shallow nonmarine inland lakes that apparently sustain growth only after an extensive evaporative phase. In case of one of the Niuafu'ou caldera lakes (Vai Lahi), the current water composition also does not sustain in situ permineralization, and the stromatolites discovered there stopped growing about 200 years ago. Overall, soda lakes represent the best sites to study modern stromatolites, their structure, microbial ecosystem, and growth rates. Many of them have shown to produce structures strikingly similar to those of Precambrian microbialites.

Genesis of soda lakes

These data presented here and in the cited papers show that soda chemistry can arise in various climatic, geologic, and morphologic settings. We find water bodies that are soda lakes in the making that will eventually acquire mature soda chemistry, such as Nemrut Crater Lake, a lake that originated only a few hundred years ago after the last eruption of the Nemrut caldera. Other crater lakes, such as Lake Taupo in New Zealand, will never reach this state, since they have an outlet. Astonishing is also the fact that Lake Kivu and Lake Tanganyika (both with an outlet) have soda lake characteristics (Soda Lake Index for Tanganyika: 1.5) and (at least in Lake Tanganyika) grow microbialites.

It has long been stated that the type of chemistry is dependent on the proportions of the ions in the waters

Soda Lakes, Figure 2 Calcareous tufa towers in Mono Lake (*top*) and Pyramid Lake (*bottom*). These towers originally formed under water at inlets of groundwater.

delivered to it (Garrels and Mackenzie, 1967). Eugster and Hardie (1978) constructed flow diagrams that show the various possibilities of brine evolution. In case of soda lakes, the criterion is the ratio of TA/(Mg + Ca). From the distributions of the soda lakes along the plate boundaries it appears that this ratio most likely arises in areas with fresh volcanic rocks. Here, biogenic CO₂ and/or (see Lake Nemrut) volcanic CO₂ can react with fresh silicates, mobilizing Na, K, Mg, and Ca, in the necessary proportions. Ongoing weathering within the crater lakes and their hydrothermal system (as in the case of Niuafu'ou), or continuing evaporation in the terminal lakes will then lead to mature soda lake chemistry and to a CaCO₃ supersaturation of around SI = 1 that will sustain microbialite growth. However, this is only a very broad picture. When looking at Satonda and Kauhako crater lakes, we find involvement of a second process that causes the alkalinity to rise. This is sulfate reduction. Both lakes are marine-derived lakes, i.e., are filled originally with sulfate-rich seawater. Microbial disintegration of organic matter must replace the charge of the sulfate ion with that of bicarbonate ions according to

This pathway of alkalinity production in anaerobic water bodies was coined “alkalinity pump” (Kempe, 1990; Kempe and Kazmierczak, 1994), supplementing the shift toward a soda chemistry, where sulfate is available.

Summary

Soda lake waters show an excess of the total alkalinity over the charges of the alkaline earth ions magnesium and calcium ($[\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] > 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}]$). They are characterized by high pH values (increasing with evaporation) and, eventually, precipitation of Na carbonates. Mature soda lakes that reach high supersaturation values with respect to calcite, aragonite, and dolomite (above $\approx$ SI 0.8) may produce cyanobacterial microbialites. The ubiquitous soda lakes in areas with fresh volcanic rocks and high weathering potential and the microbialites found therein gave rise to the *Soda Ocean Hypothesis* (see separate entry), stating that the early ocean, by following simple geological rules, should have been highly alkaline, possibly similar to present Lake Van.

SODA OCEAN HYPOTHESIS

Stephan Kempe¹, Jozef Kazmierczak²

Definition

The “soda ocean hypothesis” (SOH) stands for the concept of an early (i.e., in essence Precambrian) alkaline or even highly “alkaline ocean,” in analogy to the chemistry of the present-day “soda lakes.”

Soda ocean hypothesis (SOH)

The SOH has been advanced in biology (e.g., Snyder and Fox, 1975) for biochemical reasons before it was developed in earth sciences for geochemical reasons (Kempe and Degens, 1985; Kempe et al., 1989; Kempe and Kazmierczak, 1994).

In *biology*, the SOH rests on the observations that certain reactions considered essential for biogenesis would be favored by alkaline conditions (e.g., Abelson, 1966). One of those is the experimental observation that peptide bonds are more stable in alkaline than in acidic environments (e.g., Dose and Rauchfuss, 1972).

In *earth sciences*, the SOH rests on elemental mass balances, thermodynamic and kinetic arguments, and the analogy to modern soda lakes. These arguments are in short:

1. A CO_2 -rich atmosphere in the presence of water would react vigorously with the highly meta-stable, widespread, fine-grained glassy silicates from impacts and volcanic eruptions as would be present during the period of the terminal cataclysm in the Hadean. Carbonic acid weathering of silicates (“Urey Reaction”) will liberate cations in equivalence to the consumed carbonic acid, producing bicarbonate and carbonate as anions.
2. Continental silicate weathering today (aided by high soil PCO_2 due to biological activity; $\text{PCO}_2 = \text{CO}_2$ Pressure) consumes annually $0.15 \cdot 10^9 \text{ t C}$ (Hartmann et al., 2009); thus today’s volume of atmospheric CO_2 would be consumed in about 5,000 years by the Urey Reaction. This rate suggests that a high PCO_2 atmosphere is not stable on geological timescales.
3. Other primordial acids, such as HCl , have much less mass and therefore the primordial ocean must have had TA (total alkalinity $\equiv [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] > [\text{Cl}^-]$).
4. Sulfur-based acids were not available in larger quantities since not enough free oxygen was in the system to allow formation of either sulfurous or sulfuric acids.
5. The entire mass of carbon available in crustal compartments (i.e., $65.5 \cdot 10^{21} \text{ gC}$) as carbonates and organic carbon today could in principle have been dissolved as alkali carbonates in the oceans - as long as H_2O and CO_2 were degassed at similar rates - because this would amount to $48.5 \text{ gC/kg H}_2\text{O}$ while Na_2CO_3 is solvable at $53 \text{ gC/kg H}_2\text{O}$ (Kempe and Degens, 1985).
6. Observations of modern soda lakes show that their tributaries have inputs of $[\text{Na}^+] + [\text{K}^+] > [\text{Cl}^-] + [\text{SO}_4^{2-}]$ and $[\text{Ca}^{2+}] + [\text{Mg}^{2+}] < [\text{TA}]$ (Garrels and Mackenzie, 1967). When evaporated these waters will become alkaline because Ca and Mg carbonates (and sulfates in modern settings) will reach saturation first and Na and K carbonates will stay in solution causing increasingly higher alkalinity and pH. Soda lakes (i.e., lakes with an excess in Na-carbonates) almost exclusively occur today in or near volcanic regions. The early ocean (as well as possible primordial oceans on other planets such as Mars; Kempe and Kazmierczak, 1997) could have reacted the same way, storing CO_2 as TA as quickly as CO_2 was degassed from the mantle or deposited on Earth by comets.

These arguments are based on simple acid–base reactions but have several *derivatives*:

1. The atmosphere could not have had a high enough PCO_2 to counterbalance the lower insolation of the “faint early sun”.
2. In alkaline waters SiO_2 can be kept in solution in high concentrations (at least in the primordial seas where

Definition

The “soda ocean hypothesis” (SOH) stands for the concept of an early (i.e., in essence Precambrian) alkaline or even highly “alkaline ocean,” in analogy to the chemistry of the present-day “soda lakes.”

Soda ocean hypothesis (SOH)

The SOH has been advanced in biology (e.g., Snyder and Fox, 1975) for biochemical reasons before it was developed in earth sciences for geochemical reasons (Kempe and Degens, 1985; Kempe et al., 1989; Kempe and Kazmierczak, 1994).

In *biology*, the SOH rests on the observations that certain reactions considered essential for biogenesis would be favored by alkaline conditions (e.g., Abelson, 1966). One of those is the experimental observation that peptide bonds are more stable in alkaline than in acidic environments (e.g., Dose and Rauchfuss, 1972).

In *earth sciences*, the SOH rests on elemental mass balances, thermodynamic and kinetic arguments, and the analogy to modern soda lakes. These arguments are in short:

1. A CO_2 -rich atmosphere in the presence of water would react vigorously with the highly meta-stable, widespread, fine-grained glassy silicates from impacts and volcanic eruptions as would be present during the period of the terminal cataclysm in the Hadean. Carbonic acid weathering of silicates (“Urey Reaction”) will liberate cations in equivalence to the consumed carbonic acid, producing bicarbonate and carbonate as anions.
2. Continental silicate weathering today (aided by high soil PCO_2 due to biological activity; $\text{PCO}_2 = \text{CO}_2$ Pressure) consumes annually $0.15 \cdot 10^9 \text{ t C}$ (Hartmann et al., 2009); thus today’s volume of atmospheric CO_2 would be consumed in about 5,000 years by the Urey Reaction. This rate suggests that a high PCO_2 atmosphere is not stable on geological timescales.
3. Other primordial acids, such as HCl , have much less mass and therefore the primordial ocean must have had TA (total alkalinity $\equiv [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] > [\text{Cl}^-]$).
4. Sulfur-based acids were not available in larger quantities since not enough free oxygen was in the system to allow formation of either sulfurous or sulfuric acids.
5. The entire mass of carbon available in crustal compartments (i.e., $65.5 \cdot 10^{21} \text{ gC}$) as carbonates and organic carbon today could in principle have been dissolved as alkali carbonates in the oceans - as long as H_2O and CO_2 were degassed at similar rates - because this would amount to $48.5 \text{ gC/kg H}_2\text{O}$ while Na_2CO_3 is solvable at $53 \text{ gC/kg H}_2\text{O}$ (Kempe and Degens, 1985).
6. Observations of modern soda lakes show that their tributaries have inputs of $[\text{Na}^+] + [\text{K}^+] > [\text{Cl}^-] + [\text{SO}_4^{2-}]$ and $[\text{Ca}^{2+}] + [\text{Mg}^{2+}] < [\text{TA}]$ (Garrels and Mackenzie, 1967). When evaporated these waters will become alkaline because Ca and Mg carbonates (and sulfates in modern settings) will reach saturation first and Na and K carbonates will stay in solution causing increasingly higher alkalinity and pH. Soda lakes (i.e., lakes with an excess in Na-carbonates) almost exclusively occur today in or near volcanic regions. The early ocean (as well as possible primordial oceans on other planets such as Mars; Kempe and Kazmierczak, 1997) could have reacted the same way, storing CO_2 as TA as quickly as CO_2 was degassed from the mantle or deposited on Earth by comets.

These arguments are based on simple acid–base reactions but have several *derivatives*:

1. The atmosphere could not have had a high enough PCO_2 to counterbalance the lower insolation of the “faint early sun”.
2. In alkaline waters SiO_2 can be kept in solution in high concentrations (at least in the primordial seas where

- silica-sequestering organisms such as sponges, diatoms, silicoflagellates, and radiolarians were absent).
3. The higher the TA becomes, the lower the concentration of the free Ca-ion will become because of the fact that the IAP (the ion activity product) governing CaCO_3 solubility, i.e., $\text{IAP} = [\text{Ca}^{2+}] \cdot [\text{CO}_3^{2-}]$ is dominated by the carbonate ion.
 4. In the absence of biologically controlled biomineralization (as was typical for the entire Precambrian until, at the onset of the Cambrian, enzymatic biocalcification evolved) the ocean must have been of a very high supersaturation, since the spontaneous precipitation of CaCO_3 -minerals is kinetically inhibited in natural settings. Saturation is most commonly expressed as the saturation index (SI), i.e., the quotient between the IAP and the solubility product of the mineral (K_{Mineral}). $\text{SI} = \log \text{IAP}/K_{\text{Mineral}}$. A survey of nonenzymatic carbonate CaCO_3 -precipitating environments (Kempe and Kazmierczak, 1990; Kazmierczak and Kempe, 2006) shows that these environments have an SI of +0.8 to +1 (i.e., a 10-times supersaturation) while the modern ocean has a much lower supersaturation (North Sea $\text{SI}_{\text{calcite}}$ average summer 1986 = 0.567 ± 0.096 ; Pegler and Kempe, 1988) because it is controlled by enzymatic reactions and not by inorganic precipitation. Dolomite can be supersaturated to $\text{SI} = 4$, i.e., 10,000 times its solubility product in soda lakes (e.g., Kempe and Kazmierczak, 2007). This fact, i.e., the higher carbonate mineral supersaturation of the primordial ocean is today accepted widely (e.g., Grotzinger, 1990; Arp et al., 2001).

Because the soda ocean has vanished and the present day halite ocean prevails, there must have been a transition between the two (Figure 1). This transition must have been driven by a process with a long time constant. This process

Soda Ocean Hypothesis, Figure 1 Simple representation of the timing of the rise and fall of the soda ocean due to the Urey reaction. The happy face marks the onset of multicellularity triggered by a massive increase of the free calcium ion towards the end of the Precambrian.

is thought to be the subduction of seawater with marine crust and sediments in subduction zones and the consecutive formation of continental crust. About 1 km^3 of seawater is subducted per year today. Any compound dissolved in the ocean has therefore a half-life of about 1 billion years, depending on the rate of subduction. Thus the soda ocean could in fact have prevailed for several billion years before being gradually diminished. According to the soda ocean model (Kempe and Degens, 1985), Na and K would have been transferred into feldspars of continental granodiorites and the carbon would have been deposited as CaCO_3 and kerogen on the continents where they are stored for longer times than deep sea deposits that are lost to subduction within less than 100 million years. The chloride subducted would be recycled as volcanic HCl, in a cycle quicker than continental weathering.

Consequences for biogenesis

The alkaline model has also a series of consequence for *biogenesis* and the evolution of life in the first 3.5 billion years of Earth history.

1. Thermodynamic calculations show that in highly alkaline solutions (up to the saturation of Na_2CO_3), the free $[\text{Ca}^{2+}]$ can be as low as $4 \cdot 10^{-7} \text{ mol}$ (Kazmierczak and Kempe, 2004), while, due to ion-pairs, total Ca is significantly higher. In the model calculation shown in Figure 2 seawater (i.e., a solution with high chloride and sulfate) was mixed with the natron-saturated solution based on the dilute water from Nemrut Crater Lake (-10 m), a “soda lake in the making” (see entry “*Soda Lakes*” Table 3) that leads to a free $[\text{Ca}^{2+}]$ of $1.5 \cdot 10^{-6} \text{ mol}$. Very low environmental Ca^{2+} concentrations are favorable for biogenesis because cells have to maintain a $[\text{Ca}^{2+}] < 10^{-6} \text{ mol}$ in their cytosol (e.g., Kretsinger, 1983; Carafoli, 1987). Otherwise, the proteins would be denaturalized and lose their ability to function. Thus the formation of life in an acidic and consequentially high $[\text{Ca}^{2+}]$ environment is even more difficult to understand.
2. The only macroscopic fossils throughout the Precambrian (with the exception of the Ediacara fauna and some problematic biostructures) are microbialites (stromatolites, thrombolites), biosedimentary structures produced by colonies of microorganisms. The majority of researchers accept that they have formed by the permineralization of the EPS of biofilms dominated by cyanobacteria (e.g., Riding, 2000; Altermann et al., 2006). This form of CaCO_3 -precipitation is nonenzymatic and the cyanobacteria do not instrumentalize these precipitates for functions. The high CaCO_3 -supersaturation caused by the alkaline marine condition is thus an environment in which these microbialites could have thrived easily. Today soda-lake microbialites are formed by the same processes (e.g., in Lake Van, Kempe et al., 1991; López-García et al., 2005, in Mono Lake, and in Niufo’ou caldera lakes, Kazmierczak and Kempe, 2006) while today’s

Soda Ocean Hypothesis, Figure 2 PHREEQUE mixing experiment of modern seawater (*left*) with the natron saturated Nemrut Crater Lake water (see Table 2 in entry “*Soda Lakes*”) (*right*), illustrating the possible transition of an alkaline ocean (*right*) to one dominated by halite and gypsum (*left*). After linear mixing of constituents, the solutions are adjusted to have a calcite saturation index of +1 and a $p\text{CO}_2$ of 3.5 (roughly the present atmospheric PCO_2). Note that the sharp drop in Ca concentration is accompanied by only a slight increase in alkalinity. Note also that the sulfate concentration would describe an exponential curve between 50 and 100% if subsamples were calculated for that section of the mixing experiment.

marine stromatolites are apparently growing predominantly by trapping and binding of allogene particles (e.g., Ginsburg, 1991).

- For three billion years cyanobacteria seem to be among the primary photosynthetic organisms. Most modern cyanobacteria are alkalophiles, suggesting that their evolution proceeded in alkaline environments.
- The development of eukaryotic organisms in the late Palaeoproterozoic may have also been triggered by the early ocean conditions: The gradual increase in the $[\text{Ca}^{2+}]$ ambient concentration due to the slow transition between the soda and halite dominated oceans, could have caused the geochemical stress that might have influenced the evolution of a cell nucleus by protecting the genetic material against the disruptive Ca^{2+} -influx.
- And even the onset of multicellular organisms may have been triggered by the increasing $[\text{Ca}^{2+}]$. Experiments with sponges suggest that adhesion of cells can be triggered by an increase in $[\text{Ca}^{2+}]$ in the environment (e.g., Kretsinger, 1977). Thus the appearance of faunas in Ediacara times may be the indication that the soda ocean was near its demise.
- The biomineralization that appears in many different taxa at the turn of the Precambrian/Cambrian is, in view of the SOH, a detoxification reaction to the

rapidly rising $[\text{Ca}^{2+}]$ when the ocean, as TA decreases (e.g., from 10.3 to 2.38 meq/l as in present seawater), goes through a sort of titration endpoint triggering a >10-fold increase in $[\text{Ca}^{2+}]$ (Kempe and Kazmierczak, 1994). Measurements of Ca in fluid inclusions seem to give this facet of the SOH credibility (Brennan et al., 2004; Petrychenko et al., 2005).

Counterarguments

Some arguments against the SOH were brought forward. These, however, do not really disprove the SOH:

- Models of early Earth often prescribe a long-lasting high PCO_2 -atmosphere to keep the oceans from freezing. However, it may also be argued that the lack of free oxygen in the oceans and atmosphere could have allowed for higher methane concentrations that prevented permanent freezing of Earth.
- Möller and Bau (1993), Bau and Möller (1994) state that the water of Lake Van has a positive cerium anomaly but Precambrian carbonates (or BIFs) do not. However, these authors compare water with sediments. Measurements showed that Lake Van sediments do not exhibit the same anomaly as the water body (own data, unpublished).

Outlook

The *acceptance of the SOH* in the literature is mixed. Some authors agree with it in essence (Arp et al., 2001), others accept certain aspects (such as the high CaCO_3 -supersaturation; Grotzinger and Kasting, 1993; Riding, 2000; or Mg/Ca ratios; Ries et al., 2008), and some doubt its relevance and follow own modeling lines (e.g., Morse and Mackenzie, 1998). Many papers deal with questions of the rising oxygen and sulfate, redox-reactions or certain sedimentary problems like BIF-formation or microbialite (stromatolite) structures without recurring to the overall chemical evolution of the ocean. Although the majority of researchers tend to ignore the SOH, it found entrance into several textbooks of general geology (Degens, 1989; Einsele, 1992; Bahlburg and Bretkreuz, 1998). Digital modeling appears to be not of much help - apart from stating thermodynamic conditions correctly - since the results depend on the adopted boundary conditions of the Hadean and Archean environment, which are as yet not well defined. For example, when prescribing certain PCO_2 values to avoid freezing of oceans because of the faint early sun, then no highly alkaline ocean can evolve. Future research will have to show which one of the many models explains the past of our planet and its geological and biological evolution best.

Summary

Resting on elemental mass balances, thermodynamic and kinetic arguments, and the analogy to modern soda lakes, the soda ocean hypothesis (SOH) states that the Precambrian ocean was alkaline, with a total alkalinity $> \text{Ca} + \text{Mg}$

and a high supersaturation of carbonate minerals (SI ca. 1). The soda ocean was lost slowly by subduction of seawater and replaced by the present halite-dominated ocean toward the end of the Precambrian. This facilitated the development of multicellularity and biomineralization as detoxification reactions of life against the rising Ca-concentrations. The SOH is also consistent with the widespread occurrence of stromatolites and cherts in the Precambrian.

Definition

Soil: refers to the product of mineral weathering and secondary mineral formation, (microbial) mineralization, humus formation, and the resulting element mobilization/immobilization in the upper Earth crust in a pedogenetic process involving chemical, physical, and biological activities.

Introduction

Soil is the basis of terrestrial life, particularly for agriculture, forestry, and generally land-use by man (Driessen et al., 2001). It is also the largest terrestrial ecosystem dominated by high numbers of microorganisms and soil-living animals as well as the root systems of plants. The biota within this ecosystem, not only interact but also actively shape their environment (Fiedler et al., 2002). This can be easily seen with root systems or earthworm/mole tunnels, but the metabolic activities of microorganisms by far exceed these visible alterations. Microbes are essential for the decomposition of plant litter followed by humification. The pedogenesis differs with respect to base rock material, climatic conditions, and other factors leading to soil series of different soil types. Root exudates as well as microbiological acidification and release of

chelating agents take part in mobilization and immobilization processes of mineral elements, essential or ecotoxically relevant alike, and thus are major players in import into food chains, and input into water paths or as volatiles into the atmosphere.

Soil function

The soils of the world can be characterized from a more structural or a more functional point of view (FAO-UNESCO, 2002), and the geobiologically important functions involving metabolically active soil dwellers are characterized with reference to microbiology, botany and agriculture, and zoology.

Soil function is essential for plant nutrition. The capacity to solubilize nutrients like P and minerals including K, Na, Mg, Ca, and trace elements, as well as availability of S or N are largely the product of microbial mobilization from minerals, microbial degradation of organic matter, or fixation from air (e.g., for nitrogen). Soil mineralogy largely determines the buffering capacity for minerals adsorbed to different fractions (Jones and Bassington, 1998). The sustainability of microbial activity is connected to water availability for growth, and water storage and availability are also major functions for plant growth. Detrimental processes of soil degeneration like soil acidification, desertification, clay mineral destruction, or decrease of organic contents are global problems mankind experiences which will have a large impact on socioeconomic scales.

Agriculture and nutrition in modern systems are coupled to the use of fertilizers and plant protection chemicals which can constitute a threat to the water pathways, if management of agricultural use is not performed according to the laws and provisions on soil and water protection, good agricultural practice, or integrated farming, and monitoring has to be included to ensure best practice. Soil density increases due to the use of heavy machinery which leads to soil degradation in high-yield agricultural systems the world over.

In order to assess possible problems with land-use and soil degeneration, soil science has provided a very good reference system to classify and monitor soils based on soil mechanics, soil physics, soil genesis, soil composition, and soil functions reviewed in different contexts below (IUSS Working Group WRB, 2006). As soil can be regarded as a major sink for carbon depending on land-use, this might become more important as climate change discussions are gaining impact. Generally, soils and larger views on landscape should be regarded as eminent players in global cycles (Meir et al., 2006).

Soil texture

The soil texture can be divided in the proportion of sand (S: 63 μm –2 mm), silt (U: 2–63 μm), and clay (T: smaller than 2 μm) after removing skeleton particles (larger than 2 mm). While sand soils have more than 70 volume % of sand, clay soil is mainly composed of clay (>50%) with

Soil: refers to the product of mineral weathering and secondary mineral formation, (microbial) mineralization, humus formation, and the resulting element mobilization/immobilization in the upper Earth crust in a pedogenetic process involving chemical, physical, and biological activities.

Introduction

Soil is the basis of terrestrial life, particularly for agriculture, forestry, and generally land-use by man (Driessen et al., 2001). It is also the largest terrestrial ecosystem dominated by high numbers of microorganisms and soil-living animals as well as the root systems of plants. The biota within this ecosystem, not only interact but also actively shape their environment (Fiedler et al., 2002). This can be easily seen with root systems or earthworm/mole tunnels, but the metabolic activities of microorganisms by far exceed these visible alterations. Microbes are essential for the decomposition of plant litter followed by humification. The pedogenesis differs with respect to base rock material, climatic conditions, and other factors leading to soil series of different soil types. Root exudates as well as microbiological acidification and release of

chelating agents take part in mobilization and immobilization processes of mineral elements, essential or ecotoxically relevant alike, and thus are major players in import into food chains, and input into water paths or as volatiles into the atmosphere.

Soil function

The soils of the world can be characterized from a more structural or a more functional point of view (FAO-UNESCO, 2002), and the geobiologically important functions involving metabolically active soil dwellers are characterized with reference to microbiology, botany and agriculture, and zoology.

Soil function is essential for plant nutrition. The capacity to solubilize nutrients like P and minerals including K, Na, Mg, Ca, and trace elements, as well as availability of S or N are largely the product of microbial mobilization from minerals, microbial degradation of organic matter, or fixation from air (e.g., for nitrogen). Soil mineralogy largely determines the buffering capacity for minerals adsorbed to different fractions (Jones and Bassington, 1998). The sustainability of microbial activity is connected to water availability for growth, and water storage and availability are also major functions for plant growth. Detrimental processes of soil degeneration like soil acidification, desertification, clay mineral destruction, or decrease of organic contents are global problems mankind experiences which will have a large impact on socioeconomic scales.

Agriculture and nutrition in modern systems are coupled to the use of fertilizers and plant protection chemicals which can constitute a threat to the water pathways, if management of agricultural use is not performed according to the laws and provisions on soil and water protection, good agricultural practice, or integrated farming, and monitoring has to be included to ensure best practice. Soil density increases due to the use of heavy machinery which leads to soil degradation in high-yield agricultural systems the world over.

In order to assess possible problems with land-use and soil degeneration, soil science has provided a very good reference system to classify and monitor soils based on soil mechanics, soil physics, soil genesis, soil composition, and soil functions reviewed in different contexts below (IUSS Working Group WRB, 2006). As soil can be regarded as a major sink for carbon depending on land-use, this might become more important as climate change discussions are gaining impact. Generally, soils and larger views on landscape should be regarded as eminent players in global cycles (Meir et al., 2006).

Soil texture

The soil texture can be divided in the proportion of sand (S: 63 μm –2 mm), silt (U: 2–63 μm), and clay (T: smaller than 2 μm) after removing skeleton particles (larger than 2 mm). While sand soils have more than 70 volume % of sand, clay soil is mainly composed of clay (>50%) with

only small portions of sand (<20%). Most soils in humic conditions are sandy loam (with at least 1/3 sand, 1/3 silt, and up to 1/3 loam) or sandy silt soils (with at least 1/3 sand, at least 1/3 silt, and lower amounts of loam).

These differences in texture are also reflected in mineral composition of the respective soils. While sand soil contains 80% of quartz, this mineral constitutes only 25% of clay soil. In contrast, 50% clay minerals (mostly illit and vermiculite, as well as smaller portions of montmorillonite and kaolinit) are present in clay soil while sand soil contains only 5% of clay minerals. As clay minerals show the highest buffering potential for water and mineral elements, like alkali and earth alkali elements, soil types with higher clay mineral contents show high sorption capacities. Sandy loam/silt shows the highest fertility because of a harmonized ration between water storage and sorption capacities.

Water-retention potentials are of major importance for soil functioning. While sand soil has a water capacity of only 10 volume %, 2/3 of that water (7 volume %) is bio-available. Loam has 45 volume % water capacity of which, however, only a small proportion, usually less than 12 volume %, is available to plant roots. Sand soil has the highest aeration with 30 volume % of gas-filled pores. This is dependent on the pore sizes. Pores that are smaller than 10 μm retain water. Large pores of over 50 μm diameter, in contrast, are air-filled and contain only adsorption water. Capillary water in unsaturated soil is found in pores of 5–10 μm diameter. This is important for the soil function with respect to plant growth. As plant root hairs can just about enter pores of 5–10 μm , most water transport in soil is not simply taken from water-filled pores, but has to be extracted with sucking tension. The investigation of in situ soil water, however, remains a challenge (Weihermüller et al., 2007).

Soil type

Soil types are distinguished depending on the development of soil (pedogenesis) over space and time. The formation of a soil type generally takes a long time, upward of 1000 years. The soil type also is dependent on the climatic conditions under which the pedogenesis has taken place. A typical example of this is the formation of laterite soils in tropical areas. Such soil types show strong coloration, with iron-rich red soil types dominating in most areas. This is due to mobilization and wash-out of elements released from minerals and retaining of insoluble iron(hydroxy)oxides.

The function of mineralic, climatic, and biological conditions over time leads to formation of soils defined by different horizons. These can extend over cm up to 100 m and more, depending on the conditions experienced.

Horizons and soil profiles

A visual inspection of a soil profile already leads to immediate distinction of several layers in a typical soil. In an autochthonous soil formation, the lowest typical layer

above groundwater is the C horizon, the base rock on which the soil develops. It presents the basis for the elemental composition of the soil developing on its surface.

The B horizon (subsoil) is the next layer, clearly dominated by weathering products. Immigration of clay and sesquioxides (Fe and Al-oxihydroxides) may be found to dominate such B horizons which is specified in B_v (weathering dominated), B_t (loam accumulation), and B_s (sesquioxides) subclassification.

The uppermost layer is the A horizon (topsoil) which is rich in humus resulting from degradation of leaf litter and often shows a darker color due to organic contents enriched in this horizon. The uppermost layer of humus also is specifically termed A_o horizon. In the A horizon, microbial populations are largest and metabolic activities of soil microorganisms can be shown easily by soil respiration analyses. The A horizon also is the site of dominant plant root penetration which again stabilizes and supports the soil structure as well as the microorganisms present. Again, this horizon can be subdivided into layers A_h or A_1 (uppermost layer rich in humus), A_p (altered upper layer due to ploughing) and A_e or A_2 (subsequent layer influenced by wash-out processes). A layer of litter above the topsoil horizon is formed by decaying plant material. Depending on soil type, not all horizons have to be present.

Soil biology

The animals found in soil, or edaphone, are earthworms, nematodes, insects, specifically collembolids, and moles, to name the most prominent. Their function in soil is especially to mix the soil, to draw leaves under the soil surface which accelerates decay because of higher humidity and better accessibility for microbes, and to form passages for water interflow allowing rain to enter a soil more easily.

Plant roots stabilize soil and protect from wind and water erosion. Decaying plant roots leave passages also allowing for preferential water flow. And living roots contain special tissues for aeration and therefore improve oxygen availability for microorganisms in soil. At the same time, up to 30% of plant net photosynthesis products can be excreted by the roots in the root exudates. These consist mainly of organic acids, like acetate, oxalate, malate, and citrate. These are able to feed microbes in the rhizosphere and also chelate iron and supply the plant with iron. On the other hand, these organic acids, as well as sugars and amino acids form root exudates, provide nutrition for soil microorganisms which multiply in the vicinity of roots. This constitutes the rhizosphere, the specific area found around a plant root (Watt et al., 2006). More directly associated with the plant root are the rhizoplane bacteria which colonize the surface of the plant root. Symbiotic root associations include the nitrogen-fixing rhizobial symbioses with leguminaceous plants, and the mycorrhizal mutual symbioses between fungi and plant roots. It has been stated that microbial populations structure the plant biodiversity seen above-ground by such soil-derived associations (van der Heijden et al., 2007).

The soil surface, if no plants are present, is often covered by a crust consisting of a biofilm with cyanobacteria, fungi, bacteria, and lichens. This crust will lead to covering of bare soils which will then be prone to succession with mosses and plants.

Soil microbiology

Soils are the major place of element turnover and biogeochemical cycling in terrestrial ecosystems (Crawford et al., 2005). The degradation of plant litter, decay of leaves, carcasses, feces, and wood rotting are maintained by soil microorganisms with subsequent processes of humification. In addition, denitrification, nitrogen fixation, and element mobilization are performed by the metabolic activities of soil microorganisms. The formation of humus and the binding of elements with humic and fulvic acids drive soil development, and its function for the soil ecosystem cannot be overestimated.

Populations of soil microorganisms contain eukaryotes, bacteria, and archaea. Depending on the metabolic functions prevailing, the soil generated at the site will be dominated by formation of humic and fulvic acids, like in moorlands, by high mobilization of cations, and the formation of dissolved organic matter (DOC) in luvisols and podzols (in woodlands) or tchernozem (in agricultural land and grasslands). To have an idea of the scale, in 1 hectare soil it has been calculated that 8 tons of microorganisms are present, while the edaphon makes only for 2 tons of biomass. With the smaller size of microbes, this makes for very high numbers of soil microorganisms consisting of eukaryotic, bacterial, and archaeal cells.

The eukaryotic population is dominated by fungi with minor populations of ciliates, flagellates, algae including oomycetes and amoebae including myxomycetes. Of special importance are the mycorrhizal fungi forming a mutual symbiosis with plant roots thereby influencing not only plant physiology, but also soil as the hyphae extending into soil can add to soil structure and texture (Rillig and Mummey, 2006).

The archaea found in soil include especially the anaerobic methanogens which can lead to methane exhalation. However, methane oxidation performed by other groups of related archaea, already sequester a large portion of methane in soils. Methane exhalation is more often seen from swamps and flooded areas.

The major taxa of soil bacteria are the Gram-negative proteobacteria, the cytophaga, and Gram-positive bacilli and actinobacteria. Microbial interactions are a driving force for the community structure (Wardle, 2006). Per gram dry weight of soil, usually 10^7 – 10^9 bacteria are found. However, the bacterial population so far mainly had been analyzed by plating techniques, which will allow only those to be found that are growing under the applied laboratory conditions. Estimates of direct counts have indicated higher numbers with only 1–10% of bacteria being cultivable. Modern techniques relying not on cultivation but on DNA extraction from soil with subsequent

amplification and cloning of 16S rDNA sequences give a better insight in microbial soil populations. New taxa occur by these analyses and the phylogenetic associations observed from the obtained 16S rDNA sequences show that entire branches in the phylogenetic tree of bacteria can be described. It will remain a task to now find possibilities to cultivate these organisms in order to evaluate their physiological properties. Only such new investigations will allow to assess the role of new classes of bacteria in soil function and specific pathways for microbial degradation and soil formation will be uncovered as such investigations and modeling making use of the results will progress (O'Donnell et al., 2007).

Humification

Soil organic matter is the basis for humification (Kögel-Knabner et al., 1990). The characteristics of soil organic matter have been analyzed in some detail (Schaumann, 2006). Humus (Stevenson, 1994) provides essential functions in soils. The formation of humic acids and fulvic acids is essential for A horizon development, and especially the A_h horizon of tchernozem is rich in humus. Both humic acids (brown and grey) and shorter-lived fulvic acids have been described as recalcitrant matter with turnover times of thousands of years. These figures are re-evaluated now as it becomes clear that microbial metabolism uses these recalcitrant substrates and incorporates the carbon moieties into their cell mass. However, it is clear that the humic and fulvic acids constitute a major portion of soil matter and that their specific function in water retention and mineral element adsorption contributes a great deal to soil fertility.

Humus constituents also are important for (temporal) fixation of minerals and organic exudates. Their release will be controlled by the microbiota prevalent in the environment (Watteau and Berthelin, 1994).

Summary

Soil is the basis of terrestrial life and both evolves from biological activities and in turn allows and shapes terrestrial ecosystems. Soil types can be distinguished with different compositions, functionalities, and fertilities for production in agronomy and forestry, or water quality. The development of a soil type, such as tchernozem, rendzina, and podzol (and in tropic conditions, latozol) is dependent on base rock, climate, physical and chemical weathering, and formation of humic substances which takes thousands of years. The pedogenesis, in addition, is a result of root functions and plant litter degradation. The resulting soil can be characterized in vertical direction by soil horizons, which are distinguished from the A horizon with high humus contents, over a B horizon with lower humus contents, to the C horizon mainly consisting of base rock material. Soil series attempts to combine soil types and soil structure to reveal parameters for soil function.

SPECIES (MICROBIAL)

Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization; thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy. See entry “*Microbial Communities, Structure, and Function*” for further reading.

SPELEOTHEMS

Roman Aubrecht
 Comenius University, Bratislava, Slovakia

Synonyms

Cave deposits; Cave sinters

Definition

The word “speleothem” is from Greek and means “cave deposit.” According to its origin, this term can be used for any cave deposits, but it is used mostly for secondary mineral deposits formed (precipitated) in caves. In this entry, speleothem is understood as constructively formed, new cave material. Materials originated by destructive phenomena, such as erosion, weathering, etching, biocorrosion, or bioerosion are not subjects of this entry.

Biogenic and abiogenic speleothems

Most of the speleothems originate inorganically by precipitation of various minerals from solutions. The minerals are dissolved by undersaturated fluids and precipitate when the solutions become supersaturated, e.g., by evaporation, outgassing, or pH changes. Mineralogical compositions of speleothems vary depending on the environment in which the caves are formed. The most common speleothem-forming mineral is calcite (as most of the caves are formed of limestones), forming well-known sinter forms, such as dripstones (stalactites, stalagmites) and flowstones. Locally, mostly in hydrothermally influenced cavern systems, speleothems may be formed by its rhombic modification – aragonite. Gypsum and other sulfate minerals commonly form speleothems in gypsum karst but are widespread also in other types of caves. Speleothems formed in silicate rocks (e.g., sandstones, quartzites, granites, etc., [Figure 1](#)) are relatively rare, composed mostly of various forms of silica (from opal-A to microquartz depending on its recrystallization). Other speleothems can be represented by ferroan and manganese oxides and hydroxides forming cave flowstones.

Definition

Sponges are sessile multicellular aquatic animals (Lat. Porifera = bearing pores) whose bodies have a typical body plan which allows water to pass through the animals. Sponges are characterized by a skeleton made of calcareous, siliceous spicules or horny fibers.

Sponge microbes: Bacteria and archaea that live in close and permanent association with sponges, usually in the mesohyl between sponge cells.

Introduction

Sponges are sedentary benthic organisms found in shallow waters on tropical coral reefs to the Arctic and the deep sea. Some species, however, are restricted to freshwater ecosystems. Sponges are characterized by a typical body plan built around a system of water canals and chambers (Figure 1a). Within the chambers, flagellated cells called choanocytes produce a water current that enters the sponge body through surface pores (ostia) and leaves through larger openings called oscula. Hence, sponges are filter feeders and incorporate particles from the water as energy and nutrient source. An external cell layer (pinacoderm) encloses the sponge mesohyl, a glycosidic matrix containing several cell types which perform a variety of functions. Sponge cells show a low degree of specialization and a high degree of independence so that the sponge body in some respect resembles a protozoan colony. However, sponges are, without any doubt, placed as true members of the Metazoan (Ax, 1995; Müller, 1998a, b).

Sponges have been grouped into three classes: Calcarea, Hexactinellida, and Demospongiae. Calcarea are characterized by the presence of calcareous spicules. The upgrade of this class to the phylum level has recently been proposed by Borchiellini et al. (2001). Hexactinellida are characterized by siliceous spicules of hexactine structure and syncytial tissue organization.

Demospongiae, the most numerous and diverse class, is a nonmonophyletic group (Boury-Esnault, 2006). They generally have a mineral skeleton made of siliceous spicules, but several lineages, like the common bath sponge, have no mineral skeleton but a network of fibers instead. Modern sponge phylogeny is now based on a combination of molecular methods and sponge morphological features, but sponge spicules are still important features for species determination and identification of sponges in the fossil record.

Sponges form one of the deepest radiations of the Metazoa and can be regarded as one of the oldest animal phylum still alive. The spicule record for sponges starts in the late Proterozoic (Reitner and Wörheide, 2002), while chemofossil records even indicate the presence of sponges – or their direct ancestors – already in the early Proterozoic: specific C₃₀ steranes (24-isopropylcholestanes), which are unambiguous biomarkers for demosponges, were found in 1,800 Ma old stromatolites (McCaffrey et al., 1994; Moldowan et al., 1994).

Choanoflagellates, a monophyletic group of protists which can show a colonial lifestyle, are the closest sister group of the Metazoa (Medina et al., 2001) and show a morphological resemblance to the flagellated choanocytes of sponges. It is, therefore, widely agreed that the “urmetazoa,” the last common ancestors of all Metazoa, would have many traits found in sponges (see review in Gaidos et al., 2007).

Numerous sponge species host vast amounts of microbes in their mesohyl matrix (Figure 1b and c) or sometimes in specialized cells, while others contain only few or no microorganisms at all. The former have been termed bacteriosponges (Reiswig, 1981) or high-microbial-abundance sponges (Hentschel et al., 2003) while the latter are referred to as “low-microbial-abundance sponges.” Bacterial population densities in bacteriosponges may reach 10⁸–10¹⁰ microbes per gram of sponge wet weight, while those in low-microbial-abundance sponges are within the range of natural seawater.

The first studies exploring the microbial community of sponges were based on electron microscopy and isolation of microbes and yielded invaluable information about the microorganism morphotypes and their specific location within the sponge (e.g., Wilkinson, 1978). Microbes were found to exist extra- and intra-cellularly (e.g., Vacelet and Donadey, 1977) and even inside the nucleus of sponge cells (Vacelet, 1970). More recently, the advent of molecular techniques have enabled a detailed phylogenetic description of the microorganisms associated with sponges (Hentschel et al., 2006), whereas environmental genomics have given insights into their metabolic and physiological properties (Grozdanov and Hentschel, 2007).

Phylogenetically complex, yet highly sponge-specific microbial communities were identified in numerous species over large geographical ranges (Hentschel et al., 2002). Sequences representing 16 bacterial phyla and both major archaeal lineages have been recovered to date (see

Sponges (Porifera) and Sponge Microbes, Figure 1 The sponge–microbe system (a) schematic representation of a sponge with microbes in the mesohyl (b) fluorescence micrograph of a DAPI stained tissue section of the sponge *Geodia barretti*, CC = choanocyte chamber, Ca = canal, Ce = sponge cells. Large DAPI signals represent nuclei of sponge cells, while small signals represent sponge microbes. Scale bar = 5 μ m.

review by Taylor et al., 2007; Hentschel et al., 2003, 2006). One of these phyla, the Poribacteria, represents a new bacterial phylum, which is related to the Planctomycetales and has, so far, only been found in sponges (Fieseler et al., 2004, 2006). The other microbial phyla found in sponges are also found in other environments; however, many sponge microbes seem to form, within these phyla, monophyletic, sponge-specific 16S rRNA sequence clusters, which are absent in seawater (Taylor et al., 2007; Hentschel et al., 2003, 2006).

These recent review articles provide an excellent summary of our current knowledge about the diversity and phylogenetic affiliation of sponge microbes, and this topic will therefore not be addressed here in more detail. This article, in contrast, aims to focus on the geobiological

aspects of the sponge–microbe system: the question of a long-standing relationship between sponges and microbes; the consequences of fluctuating oxygen concentrations in sponge tissue for the sponge–microbe system; and the nature and possible function of microbial processes within sponges.

Sponge microbes: secret passengers through evolutionary history?

Did sponges and their associated microbes have an ancient partnership which remained unchanged since the origin of sponges (Precambrian), or is it a more recent but stable association which pertains to date? In an extensive review of this topic, Taylor et al. (2007) propose three scenarios which may explain the occurrence of sponge-specific

microbes. Firstly, it can be the product of a symbiosis of ancient origin perpetuated through the vertical (i.e., from adult to embryo) transmission of sponge-specific microorganisms. Secondly, the association can be the product of environmental acquisition through specific (immune system recognition, presence of favorable substrate, or bacterial protective capsule) or unspecific enrichment (rare sea-water microbes get trapped, accumulated and become thus detectable in the sponge). Finally, a combination of vertical and environmental transmissions is also possible.

The strongest evidence for a long-standing, close symbiotic relationship between sponges and some microorganisms comes from the demonstration of coevolution by comparative phylogenetic studies of sponges and their associated microbes. Erpenbeck et al. (2002) used a mitochondrial marker, cytochrome oxidase subunit 1 (CO1) and showed that the derived phylogenetic trees of four out of six symbionts were largely congruent with a tree containing sequences from the corresponding host sponges. This suggests that cospeciation had occurred (Erpenbeck et al., 2002). A subsequent study indicated a high degree of host specificity between the filamentous cyanobacterium *Oscillatoria spongelliae* and various dictyoceratid sponges (Thacker and Starnes, 2003). When comparing the phylogeny of 23 geographically, morphologically, and environmentally distant sponge species (based on their 28S rDNA gene sequences) and their associated archaea (based on 16S rDNA), a genus-specific association of these sponges with Crenarchaeota of the Marine Group I was apparent (Holmes and Blanch, 2007). These results suggest close coevolution and thus, a long-term symbiosis between these archaea and their sponge hosts. Coevolution requires that the host and symbiont maintain close association over evolutionary time. Vertical transmission, the mechanism through which coevolution could occur, has been shown for numerous sponge species belonging to all three classes of Porifera (Ereskovsky et al., 2005; Sharp et al., 2007; Schmitt et al., 2007; and references therein), including in species with highly varied reproductive strategies.

A pitfall for these comparative phylogenetic studies is that the phylogeny of sponges themselves is not yet fully resolved. This is particularly true for the Demosponges where phylogeny from the subclass to the family level is still in a state of flux (Boury-Esnault, 2006). Accordingly, our understanding of symbiont evolution in sponges will continue to develop only in parallel with improvement of our knowledge about host phylogeny. A recently initiated CO1 sequencing project for taxonomically diverse sponges (www.spongebarcoding.org) may provide data to achieve this goal in the future.

Further support for a possible ancient origin of the sponge–microbe system comes from biomarker studies. Various fatty acids of probable microbial origin occur in a wide range of sponges, irrespective of host phylogeny or geographic location (Thiel et al., 1999, 2002). The apparent absence of some of these biomarkers from

marine sediments and seawater led to the suggestion that the fatty acids and their microbial producers have been present in the sponges since ancient times.

The final type of evidence for an ancient and close association between sponges and microorganisms comes from the fossil record. Reef mounds constructed by siliceous sponges and cyanobacterial mats in the early Cambrian show that sponges and microbes closely coexisted hundreds of millions of years ago (Brunton and Dixon, 1994). Whether these microbes actually lived within the sponge tissue, as modern sponge microbes do, remains, at this stage of our knowledge, unclear.

In other words, Precambrian microorganism acquisition which started as a mere hypothesis is gaining support through studies of phylogeny, biomarkers, and fossil record. Thus, there is increasing evidence for a long-standing coevolution between sponges and certain microbial lineages, which may even date back to the roots of sponge evolution in the anaerobic, microbe-dominated world of the Proterozoic. There is evidence that a close association between sponges and bacteria may even have provided some of the genetic source material for Metazoan evolution (Lakshminarayan et al., 2004).

The alternative scenario, environmental acquisition, can, however, not be ruled out for certain sponge microbes or, in some cases, may be the more likely explanation. In this scenario, it is assumed that sponge-specific microbes are in fact also present in seawater but that our techniques fail to detect them because of their rarity. In the sponge, specific enrichment of those rare microorganisms could occur as a result of a selection through the sponge immune system (Müller and Müller, 2003) or because those microbes which possess a capsule are protected from sponge cells phagocytosis and would increase in number within the sponge body, thus becoming detectable. Unspecific enrichment is also possible and could happen through the ability of sponges to filter large amounts of water through their body. The likelihood of rare microbes being detected by our current techniques is higher in a sponge than in seawater as they might accumulate and be present in high enough numbers to be found.

The third scenario proposed by Taylor et al. (2007) is a combination of both vertical and horizontal symbiont transmissions (parental and environmental acquisition, respectively) which seems the most likely scenario to explain microbial diversity that we find in sponges today (Hentschel et al., 2002).

An anaerobic world in sponges

Until recently, sponge metabolism was viewed as being based on aerobic respiration, similarly to all Metazoa. Oxygen is usually supplied in excess to the sponge body through the water current created by the choanocytes (flagellated cells) (Reiswig, 1974). The remarkable ability of sponges to pump large amounts of water through their bodies has led to the assumption that permanent oxygen saturation exists within the sponge body. However, the

presence of anaerobic microbes in some sponge species hinted toward the presence of spatial or temporal anoxic niches (e.g., Webster et al., 2001; Hoffmann et al., 2005a; Schläppy et al., 2010a).

Gatti et al. (2002) and Schönberg et al. (2004) were the first to use microsensors to investigate the oxygen distribution in the tissue of living sponges at a microscale. Gatti et al. (2002) used oxygen micro-optodes on sponges' primorpha (multicellular aggregates composed of previously dissociated single sponge cells) and described oxygen deficiency in *Suberites domuncula*. Clark-type oxygen microelectrodes have since been used to explore the fine-scale oxygen dynamics in several sponge species from the Mediterranean and the North Atlantic. Anoxic regions have been detected in the cold-water sponge *Geodia barretti* (Hoffmann et al., 2005a) and in its explants (Hoffmann et al., 2005b), as well as in the Mediterranean sponges *Dysidea avara* (Schläppy et al., 2007) and *Chondrosia reniformis* (Figure 2) kept in aquaria or cultivation tanks with recirculating seawater.

Similarly, fluctuating oxygen concentrations leading to anoxia lasting up to 1 h were also found in *Dysidea avara* in the field when measured with an oxygen microelectrode applied by SCUBA diving (Schläppy et al., 2010a). A positive correlation between pumping activity and oxygen content was described in the tissue and in the exhaled water of *Dysidea avara* (Schläppy et al., 2007) and *Aplysina aerophoba* (Hoffmann et al., 2008). When the sponge ventilated, its body was oxygen saturated. Figure 2a shows a typical profile of a pumping sponge, with oxygen saturated water above the sponge surface and near-saturated water within the sponge tissue (compare also Hoffmann et al., 2007; Schläppy et al., 2007).

Oxygen concentrations decreased dramatically when pumping activity ceased. After 15 min without ventilation, the entire sponge body was anoxic with the exception of a 1 mm surface layer where oxygen penetrated due to molecular diffusion over the sponge surface (Hoffmann et al., 2008).

Oxygen profiles are typically diffusive over the surface and into the tissue of a nonpumping sponge (Figure 2b) (compare also Hoffmann et al., 2005b, 2008; Schläppy et al., 2007, 2010a). In situ, many sponge species reduce or even stop their pumping activity for several hours at irregular intervals (Reiswig, 1971; Vogel, 1977; Pile et al., 1997). It remains unclear whether the interruption of ventilation is caused by external events such as, for example, a high sediment load in the water (Gerodette and Flechsig, 1979; Leys et al., 1999), decrease in salinity (Fell et al., 1989), or by an intrinsic rhythm specific to a species (see Reiswig, 1971). In nonpumping sponges, molecular diffusion across a diffusive boundary layer at the sponge surface is the only source of oxygen.

The consequences of these findings are twofold. Firstly, all sponge cells and microbes which lay as deeper as 1 mm below the sponge surface need to be able to survive without direct and regular access to oxygen. Since a lack of ventilation causes tissue anoxia, the parts of the sponge

body which are not affected by surface diffusion must be alternately exposed to oxic and anoxic conditions. Secondly, by modulating the presence or absence and the magnitude of water flow through their bodies sponges have the possibility of actively switching between aerobic and anaerobic metabolism. It follows that sponge-associated microorganisms must be able to tolerate both situations and their metabolism may be activated or inactivated depending on the oxygen concentration in the sponge. This means that anaerobic microbial processes, such as sulfate reduction, for example, may take place (Hoffmann et al., 2005a; but see Schläppy et al., 2010b).

Another possible consequence of varying oxygen concentrations in sponge tissue is reported by Müller et al. (2004a, b). Using *Suberites domuncula* and its alphaproteobacterial symbiont (SB2) as a model system, they showed that the expression of genes which were essential for metabolic interaction of microbe and host was maximal under aerated conditions. Coupled with the observed loss of SB2 cells from the sponge surface under low-oxygen conditions, it was concluded that the oxygen level is responsible for regulating the bacterial fauna in *S. domuncula*. Whether this type of mechanism is equally important in other sponge-microbe systems remains to be investigated.

Tissue anoxia in sponges may act as a controlling factor toward the number of anaerobic sponge-associated microbes and act as a regulator of the nature and extent of their metabolic activity. Alternatively, it may act as a mechanism through which the sponge can kill undesirable seawater microbes. Regardless of whether anoxia in sponges is intentional or inevitable, many sponges can survive long periods of tissue anoxia and either tolerate or even foster anaerobic microbes and corresponding anaerobic microbial activity within their bodies. A close association with a diverse microbial community including (facultative) anaerobic or microaerophilic microorganisms may have been particularly advantageous at a time when fluctuating oxygen conditions were present on the Earth.

Interactions between sponges and sponge microbes

While our knowledge about phylogeny and metabolic capacities of the sponge microbes continuously increases, the role that microbes play for the sponge host is still a matter of debate. Microbes undoubtedly benefit from the nutrient-rich and protected environment of the sponge mesohyl, but the benefit to the sponge host remains unclear.

Sponge microbes may consume carbon sources which are not accessible to the sponge and may be subsequently ingested by the sponge cells. This process is commonly known as "microbial farming" and is well described (Wilkinson and Garrone, 1980; Ilan and Abelson, 1995; Vacelet et al., 1996 and own observation). Autotrophic

Sponges (Porifera) and Sponge Microbes, Figure 2 Oxygen profiles above and within *Chondrosia reniformis* showing (a) a pumping specimen with oxygen-saturated water above the sponge surface and near-saturated water within the sponge (b) a nonpumping specimen with oxygen-saturated water up to 1.5 cm above the sponge surface, a gradual decrease in the diffusive boundary layer and low oxygen concentration approaching anoxia from 2.5 cm into the sponge body. Note the different Y axes.

symbionts transform inorganic carbon (DIC) into organic carbon, which may then be transferred to the host. Energy transfer between symbiont and sponge is best described for phototrophic symbionts (e.g., cyanobacteria: Wilkinson, 1983). Chemolithotrophic processes, such as nitrification, are similar in principle. The energy which is needed for carbon fixation, however, is gained by a chemical process, the aerobic oxidation of ammonium to nitrite first and then of nitrite to nitrate. The presence of nitrifying microbes as well as the transformation of

ammonium to nitrite and nitrate have been demonstrated in many sponge species (e.g., Diaz and Ward, 1997; Diaz et al., 2004; Bayer et al., 2007; Schläppy et al., 2010b). In addition to carbon fixation, these microbes efficiently remove the sponge waste product ammonium and the toxic nitrite. Heterotrophic microbes consume simple compounds (dissolved organic carbon, DOC), while sponge cells prefer small particles such as pelagic bacteria or phytoplankton (Willenz, 1980; Pile et al., 1996; Witte et al., 1997; Ribes et al., 1999). Some sponges, however,

have been identified as important DOC sinks (Yahel et al., 2003; de Goeij et al., 2008). Interestingly, these sponges host high amount of associated bacteria. This leads to the conclusion that DOC is consumed by the sponge microbes, which in turn may be consumed by the sponge cells. A diverse community of associated microorganisms with high metabolic diversity is able to metabolize a wide array of simple molecules and to transfer them into biomass as a food resource for the sponge.

The second possibility for a mutual interaction between sponges and microbes lies within the production of secondary metabolites. Sponges produce a large variety of bioactive compounds (Blunt et al., 2003; Paul and Puglisi, 2004), which act as defenses against surface fouling, infection, or predation. Sponge microbes, which are obviously not harmed by the antimicrobial metabolites, are in fact often the actual producers of these compounds (Hildebrand et al., 2004; Piel, 2004, 2006). In addition to protecting the sponge, secondary metabolites act as a controlling factor in the host–microbe interaction.

At least some groups of sponge microbes are clearly beneficial to the sponge host, while others may be commensals.

Summary

Sponges are amongst the most ancient Metazoans on the Earth and are distributed over a wide range of aquatic ecosystems. Phylogenetically complex, yet highly sponge-specific microbial communities live in close association with numerous sponge species. A combination of both vertical and horizontal symbiont transmissions (parental and environmental acquisition, respectively) seems the most likely scenario to explain microbial diversity that we find in sponges today. Tissue anoxia is a feature found in several sponges species and is related to sponge pumping activity. Sponge microbes with autotrophic, heterotrophic, aerobic, or anaerobic metabolisms may contribute to the nutrition of the host. Other interactions between sponges and sponge microbes involve the synthesis of secondary metabolites. Due to modulation of internal oxygen concentration and the production of secondary metabolites, sponges are able to control their microbial communities. While our knowledge about the phylogeny of sponge microbes is increasing rapidly, many questions concerning the activity of sponge microbes and their interaction with the host sponge still remain unanswered. Future challenges will involve linking microbial phylogeny to microbial function on a microscale within the sponge tissue, and to examine the complex interactions within the sponge–microbe system from the origin of Metazoan life until today.

STROMATACTIS

Roman Aubrecht

Comenius University, Bratislava, Slovakia

Definition

Stromatactis is defined as a mass of spar (with partial substitution of internal sediment) which has smooth base, digitate roof, occurs in swarms and has reticulate distribution (Bathurst, 1982). Neuweiler et al. (2001) distinguished the terms “stromatactis,” “inhibited stromatactis,” and “aborted stromatactis” (Figure 1). Stromatactis originated when early internal sedimentation occurred in the open space of the cavity network followed by centripetal cementation by early marine cements in residual cavity space. Aborted stromatactis resulted from internal sediment filling of the entire or near-entire original cavity network. Inhibited stromatactis refers to incipient marine cementation of the stromatactid cavity followed by entire or near-entire internal sediment filling.

Stromatactis often (but not always) occur in mud-mounds (see entry [Mud Mounds](#)). Spar bodies similar to stromatactis but not fitting to all the points of this definition are termed in literature as “stromatactoid” or “stromatactis-like” bodies. Similar to stromatactis but smaller are fenestral pores occurring in intertidal limestones. Similar to limestones with stromatactis structures are “zebra limestones” in which the spar bodies are flat, straight, elongated, and the individual spar layers are not always interconnected.

Evolution of the term stromatactis

The term stromatactis was first used by Dupont (1881, 1882). Until present, there is still no agreement in the way of its origin. There are two main groups of opinions about the origin of stromatactis: abiogenic and biogenic. Most researchers agree that stromatactis originally represented cavities which were later filled with internal sediment and sparry calcite. The suggested abiogenic origins for stromatactis included internal erosion and reworking of small cavities (e.g., Kukal, 1971; Wallace, 1987; Bridges and Chapman, 1988; Matyszkiewicz, 1993, 1997), dewatering or escape of fluids (Heckel, 1972; Desbordes and Maurin, 1974; Bernet-Rollande et al., 1981), slumps (Schwarzacher, 1961), and freshwater karstification (Dunham, 1969). Most recent ideas involve frozen clathrate hydrates in the calcareous mud, after which the stromatactis cavities remained (Krause, 2001) or the cavities are interpreted as a result of sedimentation of stirred polydisperse sediment (Hladil, 2005; Hladil et al., 2006; Hladil et al., 2007). Some researchers supposed that stromatactis did not represent cavities and originated either by neomorphism or recrystallization of the calcareous mud (Black, 1952; Orme and Brown, 1963; Ross et al., 1975) or by dynamic metamorphism (Logan and Semeniuk, 1976). Definition

Microbialite: “Organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding sediment and/or forming the locus of mineral precipitation” (Burne and Moore, 1987), or “Benthic microbial deposits” (Riding, 1991).

Introduction

In this encyclopedia, microbialite is discussed under two chapters: (1) modern and (2) fossil. This part discusses modern microbialites, with emphasis on processes of formation. The fossil extension and classification of microbial deposits (fossil forms being more diverse) are treated in the “fossil microbialite” section of the encyclopedia (see Chapter *Microbialites, Stromatolites, and Thrombolites*). Microbialites are composed of trapped, bound, and/or precipitated sediment, and exhibit a range of mineralogies (Figure 1). This chapter focuses on carbonate microbialites, which are the most widespread and the most studied.

Microbialites are “rocks” that are produced, induced, or influenced by benthic microbial communities, primarily bacteria and sometimes also microeukaryotes, such as diatoms. These microbial communities are organized in mats or biofilms (e.g., Stolz, 2000), consisting of microscopic organisms enveloped in an organic matrix of extracellular polymeric substances (EPS; Decho, 1990; Bhaskar and Bhosle, 2005; see Chapter *Extracellular Polymeric Substances (EPS)*). Because the microbial mat is dominantly organic, it is rarely preserved in the fossil record. In some unusual cases, exceptional taphonomic conditions can preserve intact cells and even the EPS structure (e.g., silicification or preserved remnants of EPS matrices, Golubic and Hofmann, 1976; Barbieri et al., 2004; Barbieri and Cavalazzi, 2005; Altermann et al., 2006; Benzerara et al., 2006; Kumar and Pandey, 2008; Lepot et al., 2008). More commonly, the organic matter decomposes to carbon dioxide (CO₂) or methane (CH₄), although in some cases incomplete degradation can lead to organic matter enrichment of the sediment. Evidence of the original microbial mat or biofilm is generally indirect (e.g., specific sedimentary (bio)structure, micromorphology, organic biomarkers, and stable isotopic fractionation). Microbial mats can help preserve sedimentary structures in the fossil record (“microbially-induced sedimentary structures” – MISS; Noffke et al., 2003). The most

spectacular examples are carbonate microbialites. Examples of modern microbialites in the following section are followed by a discussion of processes of formation.

Types of modern microbialite

Microbialite descriptions incorporate a range of scales, from macrometers to micro/nanometers (e.g., Shapiro, 2000). Megastructure relates to the geographical extension of a microbial deposit and overall deposit morphology (e.g., ridges, biostrome, and bioherm). Macrostructure characterizes the morphology of an individual buildup (e.g., domal, branching, knobby). Mesostructure refers to structures visible with the naked eye, such as lamination. Microstructure is observed with a microscope, such as light, confocal, scanning electron (SEM), or transmission electron microscope (TEM).

Microbialite classification is based on mesostructure with four common types (Figure 2): laminated microbialites classified as stromatolites, thrombolites are clotted, leiolites are structureless, and dendrolites are dendritic (Burne and Moore, 1987; Riding, 1991, 2000; Dupraz and Strasser, 1999, 2002). All of these structures exhibit a wide range of microstructures including micropeloidal, densely micritic, or agglutinated microfabrics (Riding, 1991; Dupraz and Strasser, 1999). Three types of modern microbialites are described in the following section; dendrolites have not yet been found in modern environments. For further description of microbialite classification and microstructure see Chapter *Microbialites, Stromatolites, and Thrombolites*.

Stromatolite

The term stromatolite is derived from the Greek “stroma,” meaning mattress or stratum and “lithos,” meaning rock. The term was first introduced by Kalkowsky in 1908 to refer to “laminated benthic microbial deposits” (see also Riding, 1999; Chapter *Microbialites, Stromatolites, and Thrombolites*). The first modern stromatolites were found in the Shark Bay, Western Australia in 1954 in the hypersaline water of Hamelin Pool. Until this date, scientists believed that stromatolites were extinct, found only in the fossil record. Although the biogenicity of 3.5 Ga stromatolites has been questioned (Buick et al., 1981; Lowe, 1994; Grotzinger and Knoll, 1999; Lindsay et al., 2003), all modern microbialites called stromatolites are associated with microbial communities that induce, or serve as organic substrate for, precipitation (Riding, 2000). Modern stromatolites are found in many different locations including marine, hypersaline, freshwater, and even continental environments.

Open marine stromatolites

The Bahamas hosts the only known examples of open marine stromatolites. These structures are found at a variety of locations on the margins of Exuma Sound including Schooner Cays, Lee Stocking Island, Stocking Island Highborne Cay, and Darby Island (Dravis, 1983;

Carbonates

Calcite - CaCO_3
 Mg-Calcite - $(\text{Mg}_x\text{Ca}_{1-x})\text{CO}_3$
 Aragonite - CaCO_3
 Vaterite - CaCO_3
 Monohydrocalcite - $\text{CaCO}_3 \cdot \text{H}_2\text{O}$
 Protodolomite - $\text{MgCa}(\text{CO}_3)$
 Hydrocerussite - $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$
 Amorphous forms - $\text{CaCO}_3 \cdot \text{H}_2\text{O}$ or CaCO_3

Phosphates

Octacalcium phosphate - $\text{Ca}_8\text{H}_2(\text{PO}_4)_6$
 Brushite - $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$
 Francolite - $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$
 Carbonated-hydroxylapatite (dahllite) - $\text{Ca}_5(\text{PO}_4, \text{CO}_3)_3(\text{OH})$
 Whitlockite - $\text{Ca}_8\text{H}_2(\text{Mg, Fe})_2 + 2(\text{PO}_4)_4\text{I}_4$
 Struvite - $\text{Mg}(\text{NH}_4)(\text{PO}_4) \cdot 6\text{H}_2\text{O}$
 Vivianite - $\text{Fe}_3 + 2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$
 Amorphous Calcium Phosphate (at least 6 forms) variable
 Amorphous Calcium Pyrophosphate - $\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$

Sulfates

Gypsum - $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$
 Barite - BaSO_4
 Celestite - SrSO_4
 Jarosite - $\text{KFe}_3^{+3}(\text{SO}_4)_2(\text{OH})_6$

Sulfides

Pyrite - FeS_2
 Hydrotroilite - $\text{FeS} \cdot \text{nH}_2\text{O}$
 Sphalerite - ZnS
 Galena - PbS
 Hydrotroilite $\text{FeS} \cdot \text{nH}_2\text{O}$
 Sphalerite ZnS
 Wurtzite ZnS
 Greigite Fe_3S_4
 Mackinawite $(\text{Fe, Ni})_9\text{S}_8$
 Amorphous Pyrrhotite Fe_{1-x}S ($x = 0-0.17$)
 Acanthite Ag_2S

Arsenates

Orpiment - As_2S_3

Hydrated Silica

Amorphous Silica - $\text{SiO}_2 \cdot \text{nH}_2\text{O}$

Chlorides

Atacamite - $\text{Cu}_2\text{Cl}(\text{OH})_3$

Fluorides

Fluorite - CaF_2
 Hieratite - K_2SiF_6

Oxides

Magnetite - Fe_3O_4
 Amorphous Iron Oxide - Fe_2O_3
 Amorphous Mn Oxide - Mn_3O_4
 Amorphous Ilmenite $\text{Fe}^{+2}\text{TiO}_3$

Metals

Sulfur - S

Hydroxides and Hydrous Oxides

Goethite - $\alpha\text{-FeOOH}$
 Ferrihydrite - $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$
 Lepidocrocite - $\gamma\text{-FeOOH}$
 Ferrihydrite - $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$
 Todorokite - $(\text{Mn}^{+2}\text{CaMg})\text{Mn}_3^{+4}\text{O}_7 \cdot \text{H}_2\text{O}$
 Birnessite - $\text{Na}_4\text{Mn}_{14}\text{O}_{27} \cdot 9\text{H}_2\text{O}$

Organic Crystals following Lowenstam & Weiner (1989)

Whewellite - $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$
 Weddellite - $\text{CaC}_2\text{O}_4 \cdot (2+x)\text{H}_2\text{O}$
 Mn Oxalate - $\text{Mn}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$
 Earlandite - $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$
 Glushinskite - $\text{MgC}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$
 Manganese Oxalate - $\text{Mn}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$
 Sodium urate - $\text{C}_5\text{H}_3\text{N}_4\text{NaO}_3$
 Uric Acid - $\text{C}_5\text{H}_4\text{N}_4\text{O}_3$
 Ca tartrate - $\text{C}_4\text{H}_4\text{CaO}_6$
 Ca malate - $\text{C}_4\text{H}_4\text{CaO}_5$
 Paraffin Hydrocarbon
 Guanine - $\text{C}_5\text{H}_3(\text{NH}_2)\text{N}_4\text{O}$

Microbialites, Modern, Figure 1 Nomenclature and chemical compositions of minerals produced by biologically-related mineralization processes. (Modified from Weiner and Dove, 2003; data from Lowenstam and Weiner, 1989; Simkiss and Wilbur, 1989; Mann, 2001; Weiner and Addadi, 2002.)

Microbialites, Modern, Figure 2 Descriptive terminology for microbialite macro-, meso, and microfabrics. (From Kennard and James, 1986; Riding, 1991; Schmid, 1996; Dupraz and Strasser, 1999; Shapiro, 2000.)

Microbialites, Modern, Figure 3 Underwater photograph showing shallow subtidal stromatolites (Darby Island, Bahamas) with a vertical section (upper left hand insert) showing well-developed lamination.

Dill et al., 1986; Reid et al., 1995). These stromatolites are coarse grained structures, composed of ooid sand; they form in intertidal and subtidal environments, exposed to high wave energy and strong tidal currents (e.g., Gebelein, 1976; Reid et al., 2000). Many of the stromatolites exhibit well-developed laminae (Figure 3; e.g., Reid et al., 2000). The lamination results from iterative growth of different types of microbial mats on the top of the build-ups (Figure 4). Each microbial mat forms a distinct mineral product, which can be recognized in thin section and SEM (Figure 5; Reid et al., 2000). The first mat type (1) is dominated by the filamentous cyanobacterium *Schizothrix*, which traps and binds ooids. The stickiness of the mat EPS results in the trapping of particles, which are subsequently bound by the upward growth of the cyanobacterial filaments. Other microorganisms (e.g., diatoms that produce copious amounts of EPS) can also participate in trapping grains. The second mat community (2) consists of a thin biofilm with abundant heterotrophic bacteria. Precipitation of aragonite within this biofilm forms a micritic lamina, which caps the underlying ooids. The third mat type (3) is characterized by an abundance of the endolithic coccoid cyanobacterium *Solentia* spp. *Solentia* tunnels through grains, leaving bore holes filled with EPS. Aragonite precipitation within the EPS results in micritization of the grains and, when tunnels cross between grains, welds the grains together. This process forms a well-cemented layer (Macintyre et al., 2000; Reid and Macintyre, 2000; Reid et al., 2000). The in situ precipitation of carbonate, which leads to early lithification of

the stromatolite-forming mats, is a result of prokaryotic activity (Visscher et al., 2000; Reid et al., 2003a).

Dominance of prokaryotic communities on the surfaces of modern marine stromatolites, is favored by the selective environmental pressure of periodic burial by sand (Andres and Reid, 2006; Kromkamp et al., 2007). In contrast to eukaryotes, which are typically killed when buried for periods of weeks to months, prokaryotes such as cyanobacteria are able to survive and recover from long burial events (Kromkamp et al., 2007). This attribute may contribute to the success of stromatolites in modern and past environments. Eukaryotic colonization (macroalgae: e.g., *Batophora*), during week- to month-long periods of exposure disrupts the lamination resulting from the cycling of prokaryotic mats, producing intervals of crude to no lamination within the stromatolite head.

It should be noted that trapping and binding alone does not form a stromatolite. The key factor in allowing development of a lithified laminated buildup is a hiatus in sediment accretion and corresponding development and lithification of a microbial biofilm. During long hiatus periods (i.e., several weeks), surfaces infested with the coccoid bacterium *Solentia* forms thicker, well-cemented lamina of fused ooid grains. Precipitation of aragonitic needles associated with the activity of sulfate-reducing bacteria is a key feature in carbonate precipitation within Bahamian stromatolites (Visscher et al., 2000). Precipitation resulting from anaerobic heterotrophic activity is supported by isotopic data (Andres et al., 2005).

Microbialites, Modern, Figure 4 (Continued)

Factors leading to the cycling of surface communities responsible for lamination in Bahamian stromatolites are currently under investigation (Andres and Reid, 2006). Both biological and environmental factors may be important (Figure 6; Seong-Joo et al., 2000; Reid et al., 2003a). Biological factors include microbial ecological interactions, and production and consumption of organic and inorganic compounds. Extrinsic factors include temperature, light, nutrients, and hydrodynamics, which could affect the stickiness of EPS and/or sediment supply (Figure 6).

Hypersaline and saline stromatolites

In contrast to open marine environments, where modern stromatolites are rare, living stromatolites are more common in hypersaline environments. This is because microbial communities are able to cope with high salinity, whereas most eukaryotes, such as macroalgae and burrowing/grazing invertebrates, which compete with or ingest cyanobacteria and disrupt lamination, are largely excluded (Fischer, 1965; Awramik, 1971, 1982, 1992; Walter and Heys, 1985; Riding, 2006).

Stromatolites in Shark Bay, Western Australia are the most famous stromatolites thriving in hypersaline water. They are found in the Hamelin Pool Marine Nature Reserve of the Shark Bay UNESCO World Heritage Site. Ranging from 55–70 ppt throughout the year (Playford, 1990), Hamelin Pool has approximately double normal marine salinity and hosts abundant and diverse stromatolites. Shark Bay stromatolites were discovered in 1954 by Johnstone, Playford, and Chase of the West Australian Petroleum Pty. Ltd (Playford and Cockbain, 1976). They were the first modern stromatolites discovered with sizes and shapes comparable to fossil counterparts (Logan, 1961; Logan et al., 1974; Playford and Cockbain, 1976; Playford, 1979; Bauld et al., 1979; Bauld, 1981; Burns et al., 2004). Like Bahamian stromatolites, Shark Bay structures are formed by both (1) microbial trapping and binding and (2) microbial precipitation. Both processes are important in the intertidal zone, forming coarse grained sandy stromatolites. Microbial precipitation is the primary accretionary mechanism in the subtidal zone of Shark Bay, forming muddy, micritic stromatolites (Reid et al., 2003b).

As a result of the dominant sandy textures of Shark Bay stromatolites and open marine stromatolites in the Bahamas, some authors have proposed that these stromatolites are not appropriate analogs for fossil stromatolites, which are generally display fine-grained, micritic microstructures (Awramik and Riding, 1988). Despite their overall coarse-grained texture, these modern stromatolites have micritic laminae formed as a result of microbially-induced precipitation (Reid et al., 2000; Visscher et al., 2000). Moreover, the ecological model developed for Bahamian stromatolites, in which lamination results from the cycling of prokaryotic communities on the stromatolite surface, is likely applicable to the growth of Shark Bay stromatolites. Indeed, a model of iterative accretion of laminae, which record both microbial and environmental fingerprints and progressively shape the emergent morphology, may serve as a conceptual model for the growth of fossil stromatolites.

In addition to Shark Bay, living stromatolites are also present in many other saline and hypersaline environments. Several saline lakes in Australia harbor stromatolites, including Lake Thetis, near Cervantes, lakes on Rottne Island (Reitner et al., 1996), and Lake Clifton near Mandurah (e.g., Grey et al., 1990). Cyanobacterial stromatolitic domes have been described in the intertidal zone of Bermuda (e.g., Sharp, 1969; Golubic and Focke, 1978) and small crudely laminated knobs have been found in a hypersaline lake on Bonaire Island in the Netherlands Antilles (Golubic and Focke, 1978). Various islands in the Bahamas also have hypersaline lakes with well-developed microbial mats and stromatolites, including Storr's Lake on San Salvador. Storr's lake harbors alternating stromatolitic and thrombolitic buildups (Mann and Hoffman, 1984; McNeese, 1988; Neumann et al., 1988; Mann and Nelson, 1989; Pentecost, 1989; Zabielski, 1991).

Fresh water and continental stromatolites

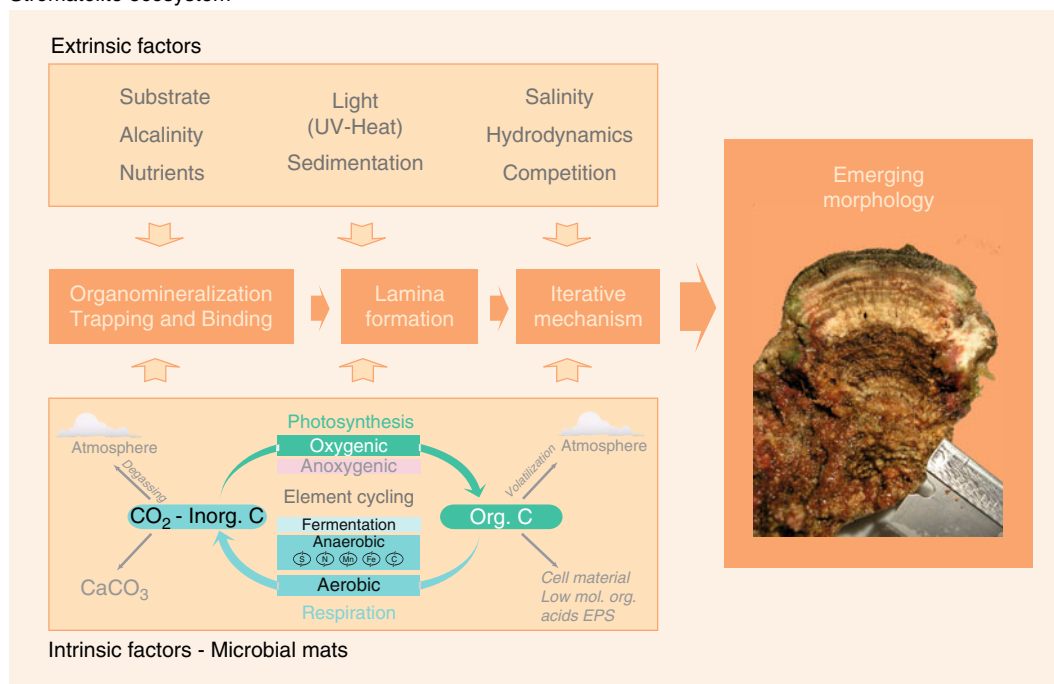

Numerous examples of freshwater laminated microbialite have been published. One of the most widespread examples of these microbialites is travertines. Tufa stromatolites (meteoene travertine following Pentecost (2005)) are freshwater fluviatile tufas, which locally exhibit thick laminated crusts formed by calcified cyanobacteria (Pentecost, 1978; Riding, 1991b, 2000). Most of the precipitation of carbonate in these travertines results from physicochemical

Microbialites, Modern, Figure 4 Model of coarse-grained open-marine stromatolite formation. (a) Cyanobacteria colonize and stabilize mobile ooid sand (trapping and binding). (b) A complex microbial mat develops in the upper few millimeters of the sediment (Cya cyanobacteria; SRB sulfate reducing bacteria; SOB sulfide oxidizing bacteria (aerobic and anaerobic); Het aerobic heterotrophs; see also Figure 8). (c–d) As a result of sediment accretion, the microbial mat migrates upward, continuing trapping and binding. Cyanobacteria (and heterotrophs) can survive massive burial. No significant in situ precipitation is observed at this stage, which corresponds to the Type 1 mat in Figure 5. (e) During a hiatus in sediment accretion, an EPS-rich biofilm develops, draping over the ooids (Type 2 mat, Figure 5). This biofilm rapidly lithifies due to the activity of anaerobic heterotrophs (i.e., SRB), forming a thin lamina of micritic aragonite (see Figure 5b4). (f) A prolonged hiatus in trapping and binding results in colonization of ooid grains under the biofilm by the endolithic cocoid cyanobacteria *Solenia* sp. (Type 3 mat, Figure 5) Precipitation of aragonite in the bore holes made by these endoliths destroys the internal microstructure of ooids, changing their color from golden brown to gray. Precipitation in bore holes crossing between grains fuses them together (Figure 5c2–4). Resumption of trapping and trapping corresponds to formation of a new Type 1 mat (e₂, f₂). The iterative succession of these three different mat types is responsible for the lamination observed in open-marine stromatolite (Figure 3).

Microbialites, Modern, Figure 5 Micrographs illustrating the main features of the surface mats responsible for the formation of modern marine stromatolites. Stromatolite lamination results from the iterative growth at the surface of the build up of three mat types: (1) Type 1 mats are dominated by filamentous cyanobacteria, which trap carbonate sand grains through EPS stickiness (A₁₋₄); (2) Type 2 mats consist of a continuous biofilm, draping the stromatolite surface (white arrows in B₁₋₃); the biofilm is composed of extracellular polymeric substances (EPS, B₃) containing numerous heterotrophic bacteria. This biofilm rapidly lithifies as a result of precipitation of aragonite needles within the biofilm (B₄); (3) Type 3 mats are characterized by endolith-infested ooid grains (yellow arrows in C₁₋₂), which appear gray and are fused together, below a surface biofilm. (A₁-B₁-C₁) binocular micrographs, (A₂-B₂-C₂) petrographic micrographs, (A₃-B₃-B₄) high vacuum scanning electron microscope images (SEM; chemical drying), and (A₄-C₃-C₄) cryo-SEM (frozen samples) images.

Stromatolite ecosystem

Microbialites, Modern, Figure 6 Interactive processes within the stromatolite ecosystem. Intrinsic (microbial mat-related) and extrinsic (environment-related) factors work together to determine the emergent stromatolite morphology and fabric, which can be described at microscale (biomineralization, trapping, and binding), mesoscale (laminae formation), and macroscale (iterative mechanism leading to morphology) levels.

degassing of CO₂ through resurgence, cascades, or waterfalls. Photosynthetic uptake of CO₂ by cyanobacteria can, however, be responsible for the precipitation of calcium carbonate in slow running and low DIC streams (Verrecchia et al., 1995; Merz-Preiss and Riding, 1999; Arp et al., 2001). Relatively low DIC and high Ca²⁺ concentration is required for photosynthesis to influence carbonate alkalinity and enable precipitation (Arp et al., 2001, 2003).

Fresh water stromatolites are also present in Antarctic lakes, which are permanently ice-covered (Parker et al., 1981). These lakes are seasonally fed by glaciers, which modify salinity from fresh-to-saline while oxygen levels vary from anoxic to supersaturated. The stromatolites are formed through sediment trapping and binding as well as carbonate precipitation in cyanobacterial-dominated (e.g., *Phormidium*, *Oscillatoria*) microbial mats. Other non-marine environments with stromatolites include alkaline lakes, such as the Caldera lakes of Niufo'ou Island (Tonga), with spectacular laminated buildups (Kazmierczak and Kempe, 2006).

Laminated deposits, referred to as terrestrial stromatolites (Verrecchia et al., 1995; Riding, 2000), are observed in "non-water-saturated" environments. These deposits have also been called lichen stromatolites (Klappa, 1979) and subaerial stromatolites (Riding, 1991b). They consist of laminar calcretes formed by microbial activity or in close association with microbial communities.

Determining between biogenic and non-biogenic calcretes is often difficult as carbonate precipitation may be caused by physicochemical evaporation (e.g., Read, 1976), and/or cyanobacterial activity (e.g., Verrecchia et al., 1995).

Thrombolite

The term thrombolite was introduced by Aitken (1967) for microbial "structures related to stromatolites, but lacking lamination and characterized by a macroscopic clotted fabric". Since this initial definition, thrombolites and stromatolites have been recognized as two distinct microbialite structures (Kennard and James, 1986). The key microstructure of thrombolites is mesoclots, which produce the clotted fabric (Shapiro, 2000). The mesoclots consist of polymorphic (simple spheroids to polylobate), millimeter to centimeter-sized, aggregates which display a variety of forms, from simple spheroids to polylobate masses (e.g., Shapiro, 2000). Clotted mesostructures have been described for many fossil thrombolites, which are mostly composed of fine-grained carbonate. Therefore, many authors define mesoclots as mostly composed of micrite or micropeloids (Kennard, and James, 1986; Dupraz and Strasser, 1999; Shapiro, 2000). However, modern thrombolites, as well examples from the Miocene, show agglutinated, clotted fabrics (Riding, 2000). The mesoclots of modern thrombolites thus consist of micrite, micropeloids, or agglutinated particles (Figure 2).

The clotted fabric of thrombolites can have a variety of origins. The fabric can be attributed “to the in situ calcification of coccoid or coccoid-dominated microbial communities” (Kennard and James, 1986). Other mechanisms involve bioturbation and bioerosion, and thrombotic mesostructures within large Bahamian stromatolites are often due to disruption of the lamination by eukaryotic colonization (e.g., *Batophora* sp. and other algae).

In some cases, environmental conditions may trigger changes between thrombolite and stromatolitic fabrics. In Storr’s Lake (San Salvador, Bahamas), well-developed thrombolites alternate with stromatolitic layers (McNeese, 1988; Mann and Nelson, 1989). This alternation might be triggered by lake-level fluctuations and associated turbidity variability. This mechanism results in a succession of phototrophic-dominated (stromatolites) to heterotrophic-dominated communities (thrombolites) as surface communities, as modeled by Dupraz et al. (2006).

Many other modern lakes host thrombolite deposits: Lake Clifton, Lake Tethys, Lake Richmond and different lakes on Rottnest Island (Australia), Kelly and Pavillon lakes (British Columbia, Canada), lakes on Bonaire Island (Netherlands Antilles, southern Caribbean; Kobluk and Crawford, 1990), Lago Sarmiento (Patagonia, Chile), Poza Azul lake (Cuatro Ciénegas, Mexico), Yellow Stone National Park (USA), Green Lake (Fayetteville, New York, USA). In addition, travertines showing thrombotic features have been referred to as “Tufa Thrombolite” (Riding, 2000).

Leiolite

The term leiolite comes from the Greek word “leios,” meaning uniform or smooth and “lithos,” (meaning rock) and was originally applied to late Miocene (Messinian) deposits in Spain (Figure 2; Braga et al., 1995). Leiolite is characterized by relatively structureless, aphanitic, mesostructure, lacking lamination or clots, and can be a synonym for “cryptomicrobial” as used by Kennard and James (1986). Most authors tend to classify microbialites as either stromatolites or thrombolites, despite the fact that many of these deposits lack the defining mesostructures and would more appropriately be termed leiolite (see Riding, 2000). No examples of modern leiolite have been published. However, examples could include non-laminated, non-thrombotic portions of Bahamian or Shark Bay stromatolites, carbonate crust formation in hypersaline lakes (Dupraz et al., 2004), and biological stabilization of sand dune by chasmolithic microorganisms (Hillgaertner et al., 2001).

Other types of microbialites

Microbial processes or the presence of microbes are often intimately related to sedimentary processes in modern carbonate systems, although the resulting deposits may not be considered as true microbialite and classified as stromatolite, thrombolite, or leiolite. These microbial carbonate

deposits include meteogene and thermogene travertine (Pentecost, 2005), where microbial influence creates specific microfabrics. Spectacular examples of travertines can be observed in many alkaline lakes, forming carbonate towers (e.g., Pyramid Lake, Nevada (Benson, 1994)), Lake Can, Turkey (Kempe et al., 1991), and Mono Lake, California (e.g., Bischoff et al., 1993; Riding, 2000). Carbonate chimneys are also formed in hydrothermal systems, where microbial activity is important (e.g., “Lost City” Hydrothermal Field; Kelley et al., 2001; Ludwig et al., 2006).

Other deposits that are difficult to classify include microbial calcrete – a terrestrial carbonate the formation of which is strongly influenced by bacteria and fungi (Jones and Wilson, 1986; Wright et al., 1988; Verrecchia and Verrecchia, 1994; Verrecchia et al., 1995). In addition, in continental environments, the formation of needle fiber calcite (NFC) is related to fungi activity (Verrecchia and Verrecchia, 1994; Cailleau et al., 2004, 2005). Mondmilch or Moonmilch – a soft paste-like or powdery cave deposit – includes important microbial populations, which influence precipitation (Thraillkill, 1976; Canaveras et al., 2006). Microbial mats are also involved in the formation of oncoids, which are unattached spherical stromatolites (e.g., Bathurst, 1966), and microbial activity may play a role in the formation of “whittings” (Thompson, and Ferris, 1990; Robbins, and Blackwelder, 1992).

Processes of microbialite formation

Early lithification is a key process in the formation of modern carbonate microbialites and is critical for the preservation of these structures in the fossil record. Lithification processes start at the time of deposition and continue during burial (diagenesis). Lithification consists of in situ precipitation of minerals, which progressively cement trapped grains (if present), and preserve the biosedimentary structures. Two closely coupled components are fundamental in carbonate precipitation within microbial mats: (1) the alkalinity engine and (2) the organic matrix in which this mineral is forming.

The alkalinity engine

The precipitation of carbonate minerals depends on the availability of carbonate ions, specific cations (e.g., Ca^{2+} , Mg^{2+}), and suitable nucleation sites. Carbonate minerals may precipitate when a solution is saturated with respect to that mineral. The degree of saturation is calculated via the saturation index of the specific mineral:

$$\text{SI} = \log(\text{IAP}/K_{\text{ps}}) \quad (1)$$

IAP is the “ion activity product” and K_{sp} is the solubility product of the corresponding mineral (solid phase). In the case of CaCO_3 , both the carbonate alkalinity and the activity of the available cations are taken into account

when calculating the saturation index (Stumm and Morgan, 1996):

$$SI_{\text{CaCO}_3} = \text{Log}(\{ \text{Ca}^{2+} \} * \{ \text{CO}_3^{2-} \} / K_{\text{sp}}). \quad (2)$$

The activity of a given chemical compound corresponds to the concentration of that compound multiplied by the activity coefficient. The solubility products for aragonite and calcite are $10^{-6.19}$ and $10^{-6.37}$, respectively, at 25°C, 1 bar atmospheric pressure and 35 PSU salinity (Zeebe and Wolf-Gladrow, 2001). A solution is supersaturated with respect to a given mineral when SI is greater than 0, meaning that K_{sp} is smaller than IAP. Experimental evidence showed that a supersaturation must be greater than 0.8 in order to have spontaneous precipitation of CaCO_3 (Kempe and Kazmierczak, 1994). Arp et al. (2001) used SI greater than 1 (i.e., a 10-fold supersaturation) as a prerequisite for carbonate precipitation in non-marine environment.

Carbonate ion activity, $\{ \text{CO}_3^{2-} \}$, depends on the carbonate equilibrium. CO_2 dissolves in water to form carbonic acid (H_2CO_3). The amount of dissolved CO_2 is proportional to the partial pressure of CO_2 ($p\text{CO}_2$) in the gas phase in contact with the liquid (i.e., Henry's Law). This value varies with pressure and temperature. Low temperature and high pressure allow for more CO_2 dissolution in water. Carbonic acid is weak acid that will only partially dissociate in an aqueous solution to produce H^+ ion and the conjugate base. It will deprotonate as follows (with pK_s value for fresh water):

The two pK_s values vary as a function of the salinity. For seawater conditions, pK_{a1} and pK_{a2} are 5.9 and 8.9, respectively (at 25°C, 1 bar atmospheric pressure and 35 PSU salinity; Zeebe and Wolf-Gladrow, 2001).

Availability of carbonate ions is a prerequisite for precipitation of carbonate minerals. The amount of bicarbonate and carbonate ions in solution denotes carbonate alkalinity, which is a part of total alkalinity, including borate, hydroxide, phosphate, and silicate. In marine and most of freshwater environments, phosphate and silicate are minor components, and the carbonate equilibrium typically drives global alkalinity. Various processes can have an impact of carbonate alkalinity, indirectly promoting precipitation or dissolution of carbonate mineral. The sum of processes that creates alkalinity represents the “alkalinity engine.” This engine is intrinsically driven when alkalinity is affected by microbial communities, or extrinsically driven when physico-chemical processes of the macro-environment cause alkalinity shifts (Figure 7).

Intrinsic alkalinity engine (metabolism)

The way microbial communities acquire their energy and their source of carbon (i.e., through metabolism) can have a strong impact on local carbonate alkalinity. In a simplified view of the microbial carbon cycle, the production of organic matter through photosynthesis (oxygenic or anoxygenic) is coupled with the oxidation of organic carbon by aerobic (oxygen as oxidant) or

Microbialites, Modern, Figure 7 Model of carbonate precipitation within biofilms. Increases in alkalinity leading to precipitation can be (a) intrinsic, resulting from microbial metabolism or (b) extrinsic, resulting from environmental factors (b). In both the cases, the EPS matrix, which embeds the microbial communities, has a pivotal role in determining mineral morphology, composition, and mineralogy.

Microbialites, Modern, Figure 8 Model of microbial mat formation by the five main guilds (van Gernerden, 1993). (a) Typical diffusion of O₂ through the water-sediment interface in the absence of microbial activity. (b) Cyanobacteria colonize the sediment, fixing (reduce) CO₂ to form biomass using solar energy (photosynthesis) and using water as electron donor. O₂ is a byproduct (visible in the upper millimeter of the depth profile). (c) The autotrophically-produced organic carbon is degraded by aerobic heterotrophs (aerobic respiration) using O₂ as final electron acceptor. The consumption of oxygen results in, or is reflected by, a sharper O₂ gradient in the sediment (arrows) and the formation of an anoxic zone below the active cyanobacterial layer. (d) Anaerobic heterotrophs then develop in the anoxic zone (mostly SRB in this example). (e) SRB produces sulfide compounds, which can then feed anoxygenic photosynthesis and aerobic sulfide oxidation. (f) Examples of a hypersaline mat from the Bahamas showing classical zonation of bacterial guilds.

anaerobic (SO₄²⁻, NO₃⁻, Fe³⁺, etc. as oxidant) respiration (Figure 8). Most microbial metabolites (products of metabolism) are efficiently recycled within the mats, completely closing the cycles of major elements. Many microbial mats function as light-driven engines, fueled only by sunlight.

The biogeochemical niche of microorganisms can be described through three overarching metabolic characteristics related to energy generation and biomass acquisition: the energy source, the electron donor used for energy generation, and the carbon source for biomass production. Each of these three properties have two possibilities: potential energy sources are light (photo-) or chemical redox reactions (chemo-), electron donors can be organic (organo-)

or inorganic (litho-), and biomass can be derived from CO₂ fixation (autotrophy) or from carbon that is already fixed (heterotrophy). For example, a cyanobacterium derives energy from light (photo) uses water as electron donor (litho) and fixes CO₂ for biomass (auto-); it is hence designated as a photolithoautotroph (trophos means “to feed”). A typical aerobic bacterium that uses organic carbon is a chemoorganoheterotroph, etc.

Different types of metabolism impact carbonate precipitation and dissolution by taking up (autotrophy) or releasing (respiration) CO₂ and through production or consumption of organic acids. Changes in organic acid concentrations modify alkalinity and pH of the mats (Ehrlich, 1996; Visscher and Stolz, 2005). Mechanisms

that can promote precipitation of carbonate minerals include the following:

1. *Oxygenic photosynthesis* (producing O_2) by cyanobacteria (photolithoautotrophy). Uptake of CO_2 during photosynthetic activity leads to precipitation of carbonate in the sheath or in the direct vicinity of the cyanobacteria (Pentecost and Riding, 1986; Frey et al. and Verrecchia, 1998, 1999; Merz-Preiss and Riding, 1999; Riding, 2000) (Figure 9). The increase in alkalinity is attributed to an exchange of HCO_3^- and OH^- through the cell membrane (Figure 9). Photosynthesis is an important mechanism for microbialite formation in freshwater environment (Arp et al., 2001), where it may help overcome the kinetic barrier for $CaCO_3$ precipitation, even in highly supersaturated freshwater settings (Shiraishi et al., 2008).
2. *Aerobic respiration* (chemoorganoheterotrophy) generally dissolves calcium carbonate through production of CO_2 . However, precipitation can occur in a well-buffered alkaline environment when CO_2 produces carbonate ions. Carbonate minerals can also be formed when aerobic respiration consumes strong organic acids and produce CO_2 that will be degassed. This process is proposed for carbonate precipitation in tropical soil associated to the oxalate-carbonate cycle (Braissant et al., 2004). In the absence of O_2 , some bacteria can generate energy through fermentation, which process uses the same compound (e.g., organic carbon, inorganic sulfur) both as electron donor and acceptor. Most fermentation of organic carbon will lead to dissolution of carbonate (Visscher and Stolz, 2005).
3. *Anaerobic respiration*: certain bacteria can oxidize organic matter using respiratory chains that do not use O_2 as final electron acceptor (also chemoorganoheterotrophy). These bacteria can use, e.g., sulfate (sulfate-reduction), nitrate (nitrate-reduction), iron (iron-reduction), manganese (manganese reduction), or even HCO_3^- . These types of metabolism can promote precipitation of carbonate through various processes (e.g., Visscher and Stolz, 2005): consumption of organic acid, production of base (e.g., NH_3), removing precipitation inhibition (removing of SO_4^{2-}), etc. Sulfate reduction is the main process in marine environment due to high concentration of SO_4^{2-} in seawater.
4. *Chemolithoautotrophy*: Some bacteria do not oxidize organic matter to generate energy. They will instead use the chemical energy (chemo) produced by the oxidation of inorganic (litho) electron donors such as H_2 , CO , Fe^{2+} , NH_4^+ and HS^- in order to fix CO_2 (autotrophy). Sulfide (in sediments) and ammonium (in the water column) oxidation are the most abundant chemolithoautotrophic electron donor in marine environment. Aerobic sulfide oxidation and ammonium oxidation is likely to induce dissolution of carbonate minerals, whereas anaerobic sulfide oxidation (e.g., using nitrate as electron acceptor) may induce

precipitation (Visscher and Stolz, 2005). However, most of these types of metabolism are all autotrophic, i.e., fixing CO_2 . The uptake of CO_2 can increase carbonate alkalinity and induce precipitation of carbonates in similar way that physicochemical degassing of CO_2 does.

Extrinsic alkalinity engine

The determination of alkalinity-driving forces that form microbialites is generally a complex task. In many cases, a combination of intrinsic and extrinsic factors is responsible for precipitation. There are however, a few examples where the macroenvironment acts as a major player in microbial mat lithification. The two important physicochemical processes that can lead to carbonate precipitation in microbial mats are water evaporation and CO_2 degassing. Even in these cases, however, the microbial communities of the mats can serve as substrates for physicochemical carbonate precipitation and affect mineral mineralogy or morphology.

In the marine environment, solar evaporation of water may lead to the formation of evaporitic minerals (e.g., Warren, 2006). Although a variety of carbonate minerals can be produced through this mechanism (e.g., calcite, ikaite, aragonite, Mg-calcite, dolomite, and magnesite), evaporites largely consist of halite and gypsum. Examples of microbial mats associated with gypsum deposits have been described (e.g., Babel, 2004). Moreover, bacteria trapped in gypsum crystals are able to survive for millions of year (Vreeland et al., 2000, 2007). The specific role of microbes in gypsum nucleation is, however, not clear as the evaporation processes generally obscure microbial signatures. For reviews on evaporites, see Yechieli, and Wood (2002) or Warren (2006).

Precipitation of carbonate can also result from degassing of CO_2 and forms travertines. Travertines represent chemically-mediated continental carbonate deposits that form around sinter sources along streams and lakes (Pentecost, 2005). The precipitated minerals, consisting of aragonite or calcite, are mainly related to the release of CO_2 from the system, resulting in supersaturation with respect to calcium carbonate. This can be illustrated by the buffering equation of the carbonate:

Removal of CO_2 through degassing will drive this equation to the right, promoting precipitation of $CaCO_3$. Similarly, increasing dissolved CO_2 drive the equation to the left, resulting in dissolution of calcium carbonate.

Travertines can be classified based on the source of the CO_2 that is degassed (Pentecost, 2005). "Metogene travertines" are formed by degassing of meteoric carbon dioxide, whereas "thermogene travertines" are formed by the degassing of hydrothermal CO_2 . In metogene travertines, the CO_2 can originate from the atmosphere or from the soil-zone. In thermogene travertines, the bulk of the CO_2

Microbialites, Modern, Figure 9 Role of photosynthesis in the precipitation of carbonate minerals. (a) Photomicrograph of *Microcoleus* spp., a filamentous cyanobacterium showing the trichoma (chains of cells) embedded in a sheath. (b) Longitudinal section through a freshwater travertine (Sarine River, Switzerland) showing precipitation of CaCO_3 in the sheath of the filamentous cyanobacteria *Oscillatoria* sp. and *Phormidium* sp. (c) Perpendicular section through the same travertine. (d) Model of photosynthetically-driven carbonate precipitation. CO_2 dissolve in water, forming bicarbonate ions (the most common form of DIC between pH 5 and 9). The bicarbonate is taken up by cells of the trichoma; the enzyme carbonic anhydrase inside the cells produces CO_2 (used for photosynthesis) and OH^- . The release of hydroxyl ions outside the trichoma increases the alkalinity in the surrounding area of the cyanobacteria and induces precipitation of CaCO_3 (provided Ca^{2+} ions are available).

EPS alteration

Intrinsic Supersaturation of EPS:

Steric Hindrance

Changes in availability of functional groups (steric hindrance).
Cation binding capacity does not reflect abundance of functional groups

Microbialites, Modern, Figure 10 Mechanistic role of the organic EPS matrix in microbial mat lithification. The exopolymeric substances are produced by various groups of bacteria (especially cyanobacteria). EPS can bind large amounts of cations (i.e., Ca²⁺), reducing the calcium carbonate saturation index, inhibiting precipitation. Alteration of the EPS matrix can end this inhibition, allowing carbonate precipitation to commence. EPS alteration is achieved via two main pathways: (1) EPS degradation, and (2b) intrinsic supersaturation of the EPS binding capacity (modified from Dupraz and Visscher, 2005).

originates from thermal processes. These hydrothermal systems are commonly associated with region of recent volcanic or tectonic activities. It is important to note that the term travertine has variable usage in the literature. Many authors use travertine only for hot water deposits, using “tufa” for cold-water deposits (Pedley, 2000). Other authors use tufa for actively-forming deposits and travertine for non-active, fossil forms (see Chapter *Tufa, Freshwater*).

Although carbonate precipitation in travertines and tufas is driven by abiotic processes, precipitation often initiates on organic substrates, e.g., leaves, woods, algae, or microbial mats. In these cases, mineralogy and morphology are strongly influenced by the organic matrix (e.g., Fouke et al., 2000; Farmer, 2000; Pentecost, 2005; Turner and Jones, 2005). Microbial mats at hot springs, for example, can therefore have a profound impact on thermogene travertine by providing templates for mineralization, even though precipitation is due to vigorous CO₂ degassing (Farmer, 2000; Fouke et al., 2000). Travertine formation is thus an example of biologically-influenced mineralization, since the carbonate precipitation is not due to biological activity, but microorganisms indirectly affect the characteristics of the resulting minerals.

The organic matrix (EPS)

Microbial communities generally produce extracellular polymeric substances (EPS; see Chapter *Extracellular Polymeric Substances (EPS)*). This organic matrix is an important part of the microbial mat, preventing desiccation, retaining essential nutrients, protecting against UV radiation, and providing water channels for transport of metabolites and signaling compounds (Decho, 1990, 2000). Cyanobacteria are often considered to be the major producers of EPS. However, many other bacteria can produce EPS matrix, including aerobic and anaerobic (chemoorgano)heterotrophs, anoxygenic phototrophs, and chemolithoautotrophs (De Philippis et al., 1998, 2001; Stal, 2000, 2003; Richert et al., 2005). Anaerobic bacteria, especially sulfate-reducing bacteria, which play a key role in carbon metabolism in marine microbial mats (Thode-Andersen, and Jorgensen, 1989; Canfield and DesMarais, 1991; Visscher et al., 1991), are known to produce large amounts of EPS (Bosak and Newman, 2005; Braissant et al., 2007).

The EPS matrix is generally the location where the carbonate minerals nucleate and grow (Dupraz et al., 2004). EPS contains negatively-charged acidic groups (e.g., carboxyl, sulfhydryl, amine, hydroxyl groups), which can bind a large amount of mono- and divalent cations, notably Ca²⁺ (Braissant et al., 2007). This binding capacity may inhibit the precipitation of carbonate minerals by depleting calcium from the surrounding microenvironment (Figure 10). The saturation index of calcite depends on the carbonate alkalinity and the availability in calcium. Even if carbonate ions are in solution, the lack of free Ca²⁺ may inhibit precipitation (Dupraz and Visscher, 2005). Therefore, the physicochemical properties of the polymer

matrix, such as the acidity or composition of the functional groups associated with the EPS, are key factors in the formation of modern microbialites.

In order to precipitate calcium carbonate in microbial mats, the Ca²⁺-binding capacity of the EPS has to be reduced. Various mechanisms have been proposed (e.g., Dupraz and Visscher, 2005), which can be grouped into two main processes (Figure 10): (1) degradation of the EPS matrix and (2) intrinsic or extrinsic supersaturation of cation-binding sites (e.g., Dupraz and Visscher, 2005). As EPS is a sugar polymer, it serves as metabolic substrate for (chemoorgano) heterotrophic bacteria. Depolymerization (hydrolysis) of EPS, possibly by fungi and heterotrophs, including spirochetes (Harwood and Canale-Parola, 1984; Weaver and Hicks, 1995), must occur before sugar monomers are available. Microbial degradation of EPS liberates the calcium and produces inorganic carbon (under alkaline conditions, the dominant species is carbonate ion). Alternatively, if the amount of Ca exceeds the number of binding sites in the EPS, free calcium will be present and available for precipitation. These conditions can be achieved through extrinsic factors (the environment) through continuous input of Ca. It can also result from the steric hindrance of acidic groups within the EPS. Although EPS may indeed possess abundant functional groups capable of binding Ca²⁺ or Mg²⁺ ions, these groups may be “sterically-inhibited” (i.e., blocked) via molecular-scale interactions into a structurally complex EPS (Figure 10).

Summary

Microbialites are “organosedimentary deposits that accrete as a result of a benthic microbial community, which traps and binds sediment and/or forms the locus of mineral precipitation” (Kennard and James, 1986). Living examples of these structures can be found in many modern environments including marine, hypersaline, freshwater, and even continental settings. Microbialites are classified based on mesostructure as stromatolites (laminated), thrombolites (clotted), and leiolites (structureless). Among the most spectacular examples are modern stromatolites, which were first discovered in a hypersaline lagoon of Shark Bay in 1954. The only known examples of stromatolites presently forming in open marine environments are in the Bahamas. Lamination in these coarse-grained structures results from the iterative growth of three different types of microbial mats on the surfaces of the build-ups. These microbial communities are responsible for successive “trapping and binding” of sediment (type 1) and in situ precipitation of calcium carbonate (types 2 and 3). Both processes are essential for stromatolites formation. Modern thrombolites and leiolites are less well-studied than modern stromatolites.

Early lithification is a key process in the formation of modern microbialites. Lithification consists of in situ precipitation of minerals, which preserves the biosedimentary structures. Two key and closely coupled components

involved in carbonate precipitation within microbial mats are (1) the alkalinity engine and (2) the organic matrix. The alkalinity engine, which effectively changes the saturation index, is *intrinsically driven* when microbial metabolism is the dominant process causing carbonate precipitation. The alkalinity engine is *extrinsically driven* when the macroenvironment is responsible for microbial mat lithification. In both the cases, the organic matrix of extracellular polymeric substances (EPS), which embed the microbial communities, is the physical location where carbonate minerals nucleate and grow. Fresh EPS contains negatively-charged acidic groups, which bind large amount of cations (e.g., Ca^{2+}), inhibiting CaCO_3 precipitation. In order to precipitate carbonate, this inhibition has to be reduced by degradation of the EPS or by oversaturation of the cation-binding capacity. Microbial activity is ultimately responsible for EPS production and degradation leading mineral precipitation.

MICROBIALITES, STROMATOLITES, AND THROMBOLITES

Robert Riding
 University of Tennessee, Knoxville, TN, USA

Microbialite Definition

Microbialites are “organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding detrital sediment and/or forming the locus of mineral precipitation” (Burne and Moore, 1987, pp. 241–242).

Introduction

Microbial carbonates are produced by the interaction of microbial growth and metabolism, cell surface properties, and extracellular polymeric substances (EPS) with mineral precipitation and grain trapping. The early lithification that is essential for the accretion and preservation of benthic microbial carbonates is both biologically mediated and environmentally dependent. Consequently, microbialite history reflects not only microbial mat evolution, but also long-term changes in seawater and atmospheric chemistry that have influenced microbial metabolism and seawater carbonate saturation state.

Microbialites are in place benthic sediments produced by microbial processes. The term “microbialite” has been most widely used to describe carbonate stromatolites, thrombolites, and similar structures that occur as domes and columns in the shallow waters of lakes and seas, but it can also apply to many additional authigenic accumulations in which microbes are locally conspicuous, such as

MICROBIALITES, STROMATOLITES, AND THROMBOLITES

Robert Riding
 University of Tennessee, Knoxville, TN, USA

Microbialite Definition

Microbialites are “organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding detrital sediment and/or forming the locus of mineral precipitation” (Burne and Moore, 1987, pp. 241–242).

Introduction

Microbial carbonates are produced by the interaction of microbial growth and metabolism, cell surface properties, and extracellular polymeric substances (EPS) with mineral precipitation and grain trapping. The early lithification that is essential for the accretion and preservation of benthic microbial carbonates is both biologically mediated and environmentally dependent. Consequently, microbialite history reflects not only microbial mat evolution, but also long-term changes in seawater and atmospheric chemistry that have influenced microbial metabolism and seawater carbonate saturation state.

Microbialites are in place benthic sediments produced by microbial processes. The term “microbialite” has been most widely used to describe carbonate stromatolites, thrombolites, and similar structures that occur as domes and columns in the shallow waters of lakes and seas, but it can also apply to many additional authigenic accumulations in which microbes are locally conspicuous, such as

some tufa, travertine, speleothem and spring, seep, and vent deposits. A series of terms and definitions were proposed between 1967 and 1987 in attempts to distinguish benthic sediments formed by microbial sediment trapping and/or precipitation. The first term, *cryptalgal*, was proposed by Aitken (1967, p. 1163) for rocks or rock structures “believed to originate through the sediment-binding and/or carbonate precipitating activities of non-skeletal algae.” The second was redefinition of *stromatolite* by Awramik and Margulis’ (1974) as “organosedimentary structures produced by sediment trapping, binding and/or precipitation as a result of growth and metabolic activity of organisms, primarily blue-green algae.” Both Aitken (1967, p. 1163) and Awramik and Margulis (1974) used blue-green algae to indicate cyanobacteria, and therefore Kennard and James (1986, p. 496) replaced *cryptalgal* by *cryptomicrobial*. The third term was *microbialite* (Burne and Moore, 1987), which effectively repeated Awramik and Margulis’ (1974) definition of *stromatolite*, thereby broadening its scope. The primary focus of all these definitions was stromatolites and thrombolites.

Research during the 1900s revealed many details concerning the nature and history of stromatolites, but it also led to nomenclatural uncertainty as it became necessary to accommodate newly recognized deposits, such as thrombolites. Aitken (1967, p. 1164) sought to clarify use of “algal” in carbonate rock descriptions by distinguishing “rocks composed of the remains of skeletal calcareous algae . . . from those formed by noncalcareous blue-green . . . and green . . . algae.” He termed the latter *cryptalgal*, defined as rocks or rock structures “believed to originate through the sediment-binding and/or carbonate-precipitating activities of nonskeletal algae” (Aitken, 1967, p. 1163). Aitken (1967, Fig. 1) regarded both thrombolites and stromatolites as *cryptalgal* deposits, distinguishing by their respective clotted and laminated macrofabrics. However, Awramik and Margulis’ (1974) proposed a broader definition of *stromatolite* as “megascopic organosedimentary structures produced by sediment trapping, binding and/or precipitation as a result of growth and metabolic activity of organisms, primarily blue-green algae.” This therefore subsumed thrombolite as a category within *stromatolite*.

As a result of these and other developments, by the 1980s stromatolites could variously be regarded as (1) microbial and laminated (e.g., Kalkowsky, 1908; Hofmann, 1969; Krumbein, 1983), (2) microbial but not necessarily laminated (Awramik and Margulis, 1974), and (3) laminated but not necessarily organic (Semikhatov et al., 1979) (see Riding, 1999, p. 324). Since the wording of Burne and Moore’s (1987, pp. 241–242) definition of *microbialite* closely followed that of Awramik and Margulis’ (1974) definition of *stromatolite*, it therefore required return to a narrower definition of *stromatolite*, as layered or laminated structures. This relatively narrow definition was intended by Kalkowsky (1908) and is implied by his term *stromatolith*; *stromat*, Greek for “to spread out,” suggests a layer. Burne and Moore’s

(1987) new term, *microbialite*, encompassed more diverse benthic microbial deposits. The outcome of these developments was that *stromatolite* and *thrombolite* could be considered as equal categories within *microbialite*, mirroring Aitken’s (1967, Fig. 1) classification of *stromatolites* and *thrombolites* within *cryptalgal* carbonates. Subsequently, these and other varieties of *microbialite* have commonly been distinguished by their dominant internal macrofabric: *stromatolite* (laminated), *thrombolite* (clotted), *dendrolite* (dendritic), and *leiolite* (aphanitic) (Riding, 2000, pp. 189–195) (Figure 1).

Given the importance of stromatolites in the development of these concepts, this orderly arrangement of terms under the *microbialite* umbrella relied heavily on stromatolites being microbial structures. However, as soon as Kalkowsky’s (1908) article was published, researchers began to point out similarities between stromatolites and abiogenic precipitates (Reis, 1908; Bucher, 1918), and this chorus has continued ever since. Logan et al. (1964, p. 69) suggested recognition of “inorganic stromatolites”; Hofmann (1973, Fig. 5) showed the difficulty of distinguishing stromatolites from other laminites; and Semikhatov et al. (1979, p. 994) proposed a descriptive rather than purely genetic definition of *stromatolite*. Reports of essentially abiogenic stromatolites have persisted, especially in the Proterozoic (Grotzinger and Read, 1983; Grotzinger, 1989a; Pope et al., 2000). Attempts to separate abiogenic and biogenic stromatolites are obstructed by *hybrid stromatolites* (see below, *Stromatolites*) consisting of millimetric alternations of abiogenic crust and lithified microbial mat (Riding, 2008). Consequently, although microbial mat models seem to apply well to all or most thrombolites, dendrolites and leiolites, they do not account for all stromatolite-like deposits, particularly in the Precambrian. The implications of this complication for stromatolite interpretation as well terminology have still to be worked out.

Microbialites in space and time

Microbes occupy a very broad range of environments, including waters of widely differing chemistry and composition, and their involvement in sedimentation is equally varied. Most microbialites are carbonate (e.g., aragonite, calcite, dolomite) in composition, but siliceous, phosphatic, iron, manganese, and sulfate examples also occur. The microbes in microbialites are dominantly bacteria, including cyanobacteria, together with small algae. From the perspective of biocalcification, *microbialite* carbonates are bioinduced. Bacteria in general exert relatively weak control over the organic site and mineralogy of calcification, and present-day microbial carbonates appear to be most widespread in environments where precipitation is inorganically favored. This environmental dependence means that where rapid cooling and degassing strongly favor mineral precipitation irrespective of organic intervention, as in hot water springs and vents, the overall sedimentary contribution of microbes may be

Microbialites, Stromatolites, and Thrombolites, Figure 1 Microbial carbonates defined by macrofabric: leiolite (aphanitic), stromatolite (laminated), thrombolite (clotted), dendrolite (dendritic). Examples show domes and associated sediment. Not to scale. All categories are integrational. In addition to domes/mounds, overall shape can include columns, layers, and irregular masses. A complication is that leiolite and stromatolite macrofabrics are defined by features within (i.e., internal to) the microbial carbonate, such as lamination. In contrast, thrombolite and dendrolite macrofabrics are defined by the external shape of individual masses of microbial carbonate, such as clots or small shrub-like masses. Thrombolitic stromatolite (Aitken, 1967), typified by some Shark Bay columns, is internally weakly clotted and crudely laminated. It is essentially agglutinated, in contrast to Neoproterozoic and early Palaeozoic thrombolites with calcified microbial microfabrics. In the latter, the clots may be prostrate and irregular, and also vertically extended into amalgamated elongate branches (e.g., *Favosamacteria*).

relatively minor. In such cases, they influence the fabric more than the process of deposition. In contrast, where waters are less saturated for minerals, microbial activity can play a major role in sediment precipitation. These differing roles are reflected in the form and fabrics of the resulting deposits.

Sensitivity to environmental influence is also reflected in the secular distribution of microbialites. Without ruling out the influence of other factors – such as competition with other organisms – marine microbial carbonate abundance through time significantly reflects fluctuation in carbonate saturation state (Fischer, 1965; Grotzinger, 1990; Riding and Liang, 2005). Microbial carbonates can therefore be relatively sensitive proxies for seawater carbonate chemistry, and for atmospheric composition, since cyanobacterial sheath calcification is promoted by increased bicarbonate uptake (Merz, 1992) when CO_2 levels decline (Riding, 2006).

Scope

The term microbialite, with its emphasis on benthic microbial deposits, encompasses a wide range of sediments; what does it not cover? “Benthic” would seem to exclude both allochthonous and interstitial microbial sediments.

If so, then biogenic “whiting” deposits produced by photo-synthetically induced nucleation of small CaCO_3 crystals in the water column are not microbialites, and neither are diagenetic bacterially induced precipitates such as cements and concretions. However, these somewhat artificial distinctions could be blurred, as in some soil crust and beachrock deposits. On the other hand, “microbial” must exclude abiogenic stromatolites, identified in both Precambrian and Phanerozoic sediments (Grotzinger and Read, 1983; Pope et al., 2000). This is a complication, especially since microbialite (Burne and Moore, 1987) is based on a preexisting definition of stromatolite proposed by Awramik and Margulis (1974), and arose from a need for a general term to encompass stromatolite, thrombolite, and related deposits. Such difficulties of definition should be resolved by increased understanding of both present-day and ancient examples of these important and geologically widespread deposits.

Stromatolites

Definition

Stromatolites are laminated benthic microbial deposits (Riding, 1991).

Introduction

Kalkowsky (1908) proposed the term stromatolite (*Stromatolith*) for columns and domes in early Triassic playa lake oolites, but similar structures were already long known from examples such as those in the late Cambrian of New York State that Steele (1825, pp. 17–18, pl. 2) described as “calcareous concretions” and Hall (1883) named *Cryptozoon* (Figure 2). The search for present-day analogs of these ancient stromatolites led from freshwater tufa (Walcott, 1914; Roddy, 1915) and marsh deposits (Black, 1933) to marginal marine domes (Ginsburg et al., 1954) and columns (Logan, 1961). These discoveries strongly supported Kalkowsky’s (1908) inference that stromatolites are essentially microbial deposits. But optimism that they could provide appropriate analogs for all ancient marine stromatolites was tempered by studies of Precambrian examples that include significant abiogenic precipitated components (e.g., Serebryakov, 1976, p. 633; Grotzinger and Knoll, 1999, p. 314). Some definitions of stromatolite have therefore encompassed both microbial and abiogenic layered/laminated authigenic crusts that characteristically form domical and columnar morphologies.

Definitions of stromatolite range from that of Kalkowsky (1908) to that of Semikhatov et al. (1979, p. 993): “a stromatolite is . . . an attached, laminated, lithified, sedimentary growth structure, accretionary away from a point or limited surface of initiation. Although characteristically of microbial origin and calcareous composition, it may be of any origin, composition, shape, size, or age.” Understanding of Kalkowsky’s view has been hindered by a definition incorrectly attributed to him by Krumbein (1983, p. 499): “stromatolites are organogenic, laminated, calcareous rock structures, the origin of which is clearly related to microscopic life, which in itself must not be fossilised.” Kalkowsky (1908) did not write this (see Riding, 1999, p. 323), but it has been repeated as if it were a literal translation from his paper (e.g., Ginsburg, 1991, p. 25; Feldmann and McKenzie, 1998, p. 201; Grotzinger and Knoll, 1999, p. 316; McLoughlin et al.,

2008, p. 96). Compounding this mistake, the somewhat awkward wording (use of “must not” rather than “need not”) has been cited as “paradoxical,” and “confusion” to be avoided, and also as an example of the deficiencies of genetic definitions (Grotzinger and Knoll, 1999, p. 316; McLoughlin et al., 2008, p. 96). In his 1908 paper, Ernst Kalkowsky did not provide a specific definition of stromatolite, but he did repeatedly emphasize that it is a laminated organic structure. He thought that the life forms involved were “*niedrig organisierte pflanzliche Organismen*” (simple plantlike organisms, Kalkowsky, 1908, p. 125). It is therefore reasonable to conclude that Kalkowsky essentially regarded stromatolites as laminated microbial deposits (Riding, 1999).

However, at the same time that support was growing for Kalkowsky’s (1908) biogenic interpretation of stromatolites, the contrary view was also being expressed. Reis (1908) interpreted stromatolites as inorganic precipitates, Bucher (1918) compared them with hot spring sinter. Semikhatov et al. (1979, p. 994) were also concerned by the similarities between microbial stromatolites and “morphologically similar structures of nonmicrobial origin” such as those in caves and hot springs, and therefore suggested their descriptive definition. Subsequent research has shown that some stromatolite-like deposits are essentially abiogenic (e.g., Grotzinger and Read, 1983; Grotzinger and James, 2000, p. 9). Pope et al. (2000, p. 1139) contrasted microbial and abiogenic stromatolites, and considered “isopachous stromatolites to have been dominated by chemogenic precipitation in the absence of microbial mats, and the growth of peloidal stromatolites to have been controlled by sedimentation in the presence of microbial mats.”

Fabric criteria can be used to distinguish abiogenic evenly layered sparry crust from fine-grained lithified microbial mats with uneven layering. In well-preserved examples, it should therefore be possible to tell abiogenic and biogenic stromatolites apart. However, as noted under microbialite, the millimetric interlayering of these two fabrics that can occur in hybrid stromatolites (Riding, 2008) makes such straightforward separation impossible. Consequently, stromatolites are regarded here, essentially, as laminated benthic microbial deposits, but they can contain abiogenic precipitates and be intimately inter-layered with them. In the marine realm, there is a strong secular perspective to this. Many Phanerozoic and Neoproterozoic stromatolites are probably essentially lithified microbial mats, whereas many older examples probably contain at least some precipitated abiogenic crust.

Microbialites, Stromatolites, and Thrombolites, Figure 2 Late Cambrian (late Franconian–early Trempealeauan) stromatolite (*Cryptozoon*), Hoyt Limestone, Petrified Gardens, Saratoga Springs, New York, USA. Coin diameter ~3 cm.

Stromatolite types

Stromatolite micro- and macrofabrics commonly intergrade with those of dendrolites and thrombolites (Figure 3). Their formation can involve up to three main processes: microbial precipitation, inorganic precipitation, and grain trapping (Figure 4). The main types represent

Microbialites, Stromatolites, and Thrombolites, Figure 3 Stromatolites and thrombolites based on micro/macrob fabric. All except wrinkled cohesive mats are syngedimentarily lithified by microbial and/or abiogenic processes. Fine-grained varieties include two distinctive types: (i) stromatolites with peloidal-microclotted microfabrics and (ii) dendrolites and thrombolites with abundant filamentous and other calcified microbial microfossils.

lithified microbial mat, sparry crust, and combinations of these (“hybrid stromatolite”).

Lithified microbial mat stromatolites exhibit a variety of intergradational fabrics. Two main types are fine-grained and coarse agglutinated. They form diverse stratiform, domical and columnar structures and, overall, tend to show relatively uneven to discontinuous layers with relatively poor inheritance and can include abundant fenestrae. Fine-grained stromatolites appear mainly to be products of syngedimentary microbial precipitation and are dominated by fine-grained (micrite, microspar) and filamentous fabrics. Fine-grained microfabrics are typically clotted and peloidal and are probably largely produced by heterotrophic bacterial calcification (e.g., dissimilatory sulfate reduction) of EPS and other cell products. Filamentous microfabrics are dominated by tubiform microfossils such as *Girvanella* that reflect photosynthetic cyanobacterial sheath calcification, but they too have fine-grained matrices. On their own, peloid-microclotted fabrics tend to be stromatolitic, and have been termed spongiostrome (Gürich, 1906; Pia, 1927, p. 36).

Filamentous fabrics tend to be more crudely layered and grade to thrombolitic. They have been termed porostromate (Pia, 1927, pp. 36–40), skeletal (Riding, 1977), and calcimicrobial (James and Gravestock, 1990). Coarse agglutinated stromatolites/thrombolites are produced by trapping sandy sediment by uncalcified EPS and erect filaments that can include microalgae. Present-day examples include some Shark Bay and Lee Stocking Island columns. They often have crudely layered macrofabrics (Logan, 1961) and have been termed thrombolitic stromatolites (Aitken, 1967).

Sparry crust (Riding, 2008) can form stromatolite-like abiogenic precipitates (Grotzinger and Rothman, 1996) characterized by even, often isopachous, laterally persistent layers with good inheritance (Pope et al., 2000). They have been most widely recognized in the Palaeoproterozoic and Mesoproterozoic (Grotzinger and Knoll, 1999, Fig. 6a, b), with microdigitate forms occupying peritidal environments (Grotzinger and Read, 1983) and isopachous laminite (Jackson, 1989) relatively deeper water facies.

Microbialites, Stromatolites, and Thrombolites, Figure 4 Stromatolitic and thrombolitic carbonates related to grain trapping, and syngenic microbial and inorganic precipitation. Developed from Riding (2008, Fig. 12). Principal categories are coarse agglutinated, fine-grained, hybrid and sparry crust. Those dominated by microbial precipitation and/or grain trapping are microbial mats. Sparry crusts are essentially abiogenic precipitates. Hybrid stromatolites are combinations of lithified microbial mat and sparry crust. Fine-grained varieties include filamentous (also termed porostromate, skeletal, and calcimicrobial) which is more thrombolitic and peloidal-microclotted (also termed spongostromate) which is more stromatolitic. Microbial mats dominated by trapping, but with relatively minor early lithification include freshwater marsh stromatolites (Black, 1933) and wrinkle marks (Runzelmarken, Häntzschel and Reineck, 1968) mainly in siliciclastic sands and silts. For secular distributions see Fig. 11.

Hybrid crust stromatolites (Riding, 2008) typically consist of light-dark, often millimetric, alternations of sparry and fine-grained crust. These build stromatolites with well-developed even, although not usually isopachous, layering that is laterally quite persistent with generally good inheritance, as in some *Conophyton* (e.g., Walter, 1972, p. 86) (Figure 5). This layering is therefore intermediate in regularity between that of stromatolite-like sparry crust and fine-grained crust stromatolites. Hybrid crust appears to be a major component of Palaeoproterozoic (e.g., Sami and James, 1996) and Mesoproterozoic stromatolites (e.g., Petrov and Semikhatov, 2001), which can include very large domical and conical examples. Laminated freshwater cyanobacterial mats in shallow lakes of Andros Island show similarities to hybrid stromatolite, with fine-grained incipiently lithified cyanobacterial mats alternating with laminar fenestrae and elongate open voids (Monty, 1976, Fig. 4). If this structure were early lithified,

it could resemble some *Conophyton* and *Baicalia* fabrics, as Bertrand-Sarfati (1976) suggested.

Intertidal mats and wrinkle structures

At the present day, intertidal and supratidal sediments are commonly colonized by cyanobacteria dominated mats in siliciclastic (e.g., Cameron et al., 1985; Stal et al., 1985), evaporitic (e.g., Gerdes et al., 2000), and carbonate (Black, 1933; Logan et al., 1974) environments (Figure 6). Where these mats are cohesive, but insufficiently early lithified, they do not show significant accretion but nonetheless stabilize layers of sediment. These microbialites that were unlithified during their formation can be preserved in place, and also imprinted and disrupted, e.g., by desiccation and water movement. They and their incorporated sediment may be cracked, curled, and folded, and this syngenic deformation can be preserved after burial. Such patterned surfaces in

Microbialites, Stromatolites, and Thrombolites,
Figure 6 Wrinkled microbial mat with carbonate sediment; supratidal flat, Crane Key, Florida Bay, USA. Red pen cap ~5 cm long.

Mesoproterozoic limestones were named *Kinneyia* by Walcott (1914, p. 107, pl. 11, Fig. 3) and subsequently linked to “Runzelmarken” (wrinkle marks, Häntzschel and Reineck, 1968) and other mat-related structures (Hagadorn and Bottjer, 1997). They have also been termed microbially induced sedimentary structures (MISS) (Noffke et al., 1996). The exact origins of these bedding plane structures are probably complex and varied (Porada et al., 2008) but they have been widely linked to deformation of microbial mats and have been used to infer the presence of mats in the Proterozoic (Horodyski, 1982) and Archaean (Noffke et al., 2006).

Siliciclastic stromatolites

In contrast to wrinkle structures, siliciclastic stromatolites can possess large domical morphologies and considerable synoptic relief. They are much scarcer than carbonate stromatolites, and are only known from mixed siliciclastic-carbonate environments that provide both siliciclastic grains and the early lithification required to maintain their support (Martín et al., 1993). Most examples are Palaeozoic, e.g., Ordovician (Davis, 1968), Devonian (Draganits and Noffke, 2004), Carboniferous (Bertrand-Sarfati, 1994), and Permian (Harwood, 1990), but diverse examples also occur in the late Miocene of South-east Spain (Martín et al., 1993; Braga and Martín, 2000). Based on the proportion of siliciclastic grains they contained, Martín et al. (1993) recognized three compositional types: “carbonate,” <10%; “siliciclastic-carbonate,” 10–50%; and “sandstone,” >50%. They are typically metric, locally decametric, domes with both stromatolitic and thrombolitic macrofabrics, associated with marginal marine beach (Braga and Martín, 2000), fan-delta and conglomeratic debris-flow deposits (Martín et al., 1993), and also with oolitic stromatolites–thrombolites (Braga et al., 1995). Sediment within the more siliciclastic domes includes abundant quartz, mica, and lithic fragment sand, and occasional quartz and metamorphic rock granules and pebbles.

Thrombolites

Definition

Thrombolites (Greek: *thrombos*, clot; *lithos*, stone) are “cryptalgal structures related to stromatolites, but lacking lamination and characterized by a macroscopic clotted fabric” (Aitken, 1967, p. 1164).

Introduction

Aitken’s (1967) seemingly straightforward definition of thrombolite contained the seeds of more confusion than might have been anticipated. Since stromatolites are generally regarded as internally laminated; it could be expected that thrombolites are internally clotted. However, stromatolitic laminae are internal features of microbial carbonate, whereas “clot” could be used to describe both the external shape and internal structure of microbial carbonate (Figure 1). Aitken’s (1967) descriptions of Cambro-Ordovician examples, and his emphasis that thrombolite clotted fabric is macroscopic, have directed most researchers to regard “clots” as centimetric patches of microbial carbonate within interstitial sediment. In this view, a thrombolite dome consists of numerous such clots within lighter colored interstitial detrital matrix. Consequently, the dome has an overall macroclotted fabric, but the individual clots themselves are not necessarily internally composed of smaller clots, although they can be. This contrasts with stromatolitic domes in which each individual stromatolite is internally laminated and its shape is described separately, e.g., as domical, columnar, digitate, etc.

Aitken's (1967) concept of clots as patches of microbial carbonate within matrix is appropriate where they are irregularly rounded, but in digitate thrombolites the patches elongate into decimetric branches (e.g., Armella, 1994, Fig. 9) and use of "clot" to describe these is awkward. If some of Aitken's (1967) thrombolite domes contain dendritic fabrics, as seems likely, then why did he stress their clotted macrofabric? A likely explanation is that, in domes composed of radial branches, any section other than a vertical one through the dome center (e.g., Armella, 1994, Fig. 9) tends to show clot-like rounded outlines of oblique sections of branches. If this is correct, then to be consistent the branches should also be regarded as clots. This approach was followed by Armella (1994) and Kennard (1994) (although they used *thromboid* as an equivalent term to clot) to describe rounded lobate patches and elongate columns alike. There seems little doubt that this is what Aitken (1967) intended, and Shapiro (2000, p. 166) recognized that he used clot to describe the thrombolite columns themselves. Nonetheless, in describing similar branched Cambro-Ordovician thrombolites (*Favosamaceria*), Shapiro (2000) and Shapiro and Awramik (2006) broadened "clot" to refer to both millimetric clots within the branches and centimetric clots embedded in interstitial sediment. And there is a further complication. Aitken (1967) suggested that poorly laminated columns at Shark Bay are "thrombolitic stromatolites." As a result, in addition to describing Cambro-Ordovician domes with well-defined fine-grained clots, thrombolite has been applied to agglutinated present-day microbial columns in which the clots are much less distinct patchy fabrics.

These complications of usage still require clarification. At present, it is safe to say that "clot" (and the equivalent terms mesoclot and thromboid) has not been used consistently in thrombolite studies. It has been applied to millimetric patches within microbial carbonate, to centimetric lobate patches and also extended columns of microbial carbonate surrounded by detrital carbonate sediment, to transverse sections of these columns (here termed pseudoclots), and to diffuse patches of trapped sand, as well as to secondarily enhanced clots. Given these complications, it is understandable that earlier workers often referred to thrombolites as "unlaminated stromatolites" (e.g., Aitken, 1967, p. 1166; Pratt, 1982a; Schopf and Klein, 1992, p. 1202). Nonetheless, thrombolites can generally be regarded as benthic microbial carbonates with macroclotted fabric.

Thrombolite types

Two main types of thrombolite are calcified microbe and coarse agglutinated (Riding, 2000, pp. 192–193). Both intergrade with microbial mat stromatolites and primarily reflect the presence of major components that form irregular aggregates rather than thin layers. Nonetheless, the two types have quite distinct origins:

- (i) *Calcified microbe thrombolites* include the classic Cambro-Ordovician examples described by Aitken (1967) and also by Pratt and James (1982) and Kennard and James (1986). Aitken (1967) noted that burrows and trilobite fragments are common in these thrombolites, and examples of similar age often show mottled interiors and stromatolitic outer coatings (Figure 7). They consist of clots composed of framework whose most recognizable components are calcified microfossils, such as *Girvanella* filaments and *Renalcis* botryoids. The clots may be irregular centimetric amoeboid forms (Figure 8) or extend vertically into elongate (Armella, 1994, Fig. 9) meandriform and laterally amalgamated (Pratt and

Microbialites, Stromatolites, and Thrombolites, Figure 7 Late Cambrian (Trempealeauan) thrombolite column with mottled interior (within dotted line) and dark stromatolitic coating (between white arrows). James, 1982, Figs. 9, 12) branches named *Favosamaceria* by Shapiro and Awramik (2006), (Figure 1). The clots are surrounded by detrital sediment infill. Progression from irregular clots to elongate branches has confused descriptive terminology. Shapiro (2000) suggested that in branched forms the clots typical of thrombolites are to be found within the branches, although Aitken (1967) seems to have regarded the columns as clots. James and Gravestock (1990) used “calcimicrobe” (calcified microbial microfossil) to refer to filamentous and botryoidal fossils that are common in Cambrian reefs. These typically form dendrolite (Figure 9) and thrombolite (Figure 10) fabrics and include calcified cyanobacteria such as *Angusticellularia*, *Botomaella*, and *Girvanella*, and also *Epiphyton* and *Renalcis*, whose affinities are less certain. Calcified microbe thrombolites are widespread in shallow marine

Mountains, Morocco. Width of view 8 cm.

environments during the Neoproterozoic and early Palaeozoic.

- (ii) *Coarse agglutinated thrombolites* are largely composed of fenestral microbially trapped sandy sediment within finer-grained microbially lithified matrix. They are closely associated with coarse agglutinated stromatolites (Figures 3 and 4) that Aitken (1967, p. 1171) described as “thrombolitic-stromatolites.” They are only known in the late Neogene and their development appears to be linked to the rise of algal-cyanobacterial mats able to trap coarse sediment.

Coarse-grained thrombolites in the late Miocene of South-east Spain are closely associated with stromatolite fabrics in composite domes and columns up to 1.5 m high and 4 m across (Martín et al., 1993; Braga et al., 1995; Feldmann and McKenzie, 1997). They include oolitic examples in which clotted fabric is produced by irregular fenestrae up to 15 mm in size (Riding et al., 1991a, p. 123). Braga et al. (1995, Fig. 8, pp. 358–359) attributed the formation of these thrombolite fabrics to “a complex of irregular agglutination, microbial calcification, skeletal encrustation, and erosional processes.”

Logan (1961) regarded Shark Bay columns as stromatolites but recognized that the lamination is often poor, describing some as “crudely laminated with laminae of 1–10 mm. in thickness” (p. 526, pl. 1, Fig. 4). Playford and Cockbain (1976, p. 403) observed that “Hamelin Pool stromatolites range from unlaminated (thrombolites) to finely laminated; most show only crudely developed lamination.” Walter (1972, p. 64) attributed “the crude lamination of many Shark Bay stromatolites” to the thick irregular mats and coarse sediment. Logan et al. (1974, p. 154) related carbonate fabric to mat type, with thick irregular pustular mat dominated by *Entophysalis* in particular producing “unlaminated to poorly laminated” fenestral fabric, and Gebelein (1974) suggested that clotted fabric could reflect degradation of organic material. Similar Bahamian subtidal columns (Dravis, 1983) are coarse-grained and crudely laminated (Dill et al., 1986) and it has been suggested that abundant algae, including diatoms in these mats contribute to the coarse texture and poor lamination typical of both Shark Bay (Awramik and Riding, 1988) and Bahamian (Riding et al., 1991b) columns.

Mesozoic-Cenozoic thrombolites: Thrombolites are also common in the mid-late Jurassic (e.g., Leinfelder et al., 1993; Parcell, 2002; Kopaska-Merkel, 2003; Mancini et al., 2004), often in association with sponges and stromatolites in deeper water (e.g., Jansa et al., 1988; Leinfelder et al., 1994, p. 37; Dromart et al., 1994) and with corals in shallow-water (e.g., Bertling and Insalaco, 1998; Dupraz and Strasser, 1999; Olivier et al., 2003; Olivier et al., 2006; Helm and Schülke, 1998, 2006). They exhibit a variety of forms, including

arborescent and pendant that commonly occur as thick crusts on frame-building invertebrates, and are also closely associated with a variety of problematic encrusting organisms such as *Bacinella*, *Lithocodium*, and *Shamovella/Tubiphytes*, as well as annelids and foraminifers (Leinfelder et al., 1993, Fig. 6; Olivier et al., 2003, Fig. 4). Similar – but more often stromatolitic – crusts occur in late Neogene, including present-day, scleractinian reefs (Riding et al., 1991c; Montaggioni and Camoin, 1993; Leinfelder et al., 1993, pp. 222–224), and provide important clues to the formation of microbial carbonate microfabrics (Reitner, 1993; Reitner et al., 2000). In addition, the macrofabrics of these Mesozoic-Cenozoic examples broadly resemble those of early Palaeozoic calcified microbe thrombolites, but with significantly different skeletal components. Their microfabrics are fine-grained, with peloids and microclotted micrite (Olivier et al., 2006, Fig. 9), similar to those of many lithified microbial mat stromatolites.

Tufa thrombolite and stromatolite (Riding, 2000, pp. 191, 194) forms in calcifying lakes and streams as a result of cyanobacterial calcification that includes sheath impregnation and encrustation, together with calcification of associated microbes. It was comparisons with freshwater tufa that first led to recognition of links between stromatolites and cyanobacteria (Walcott, 1914; Roddy, 1915). These complex fabrics show considerable variety due to local differences in organisms and the extent of biocalcification and external encrustation. There are similarities between tufa stromatolites and hybrid crust stromatolites (Riding, 2008, p. 88) (Figure 4).

Kennard and James (1986, p. 498) noted that, although “poorly laminated and partially clotted microbial structures” occur on some present-day hypersaline marine shorelines (Laguna Mormona, Shark Bay) and in some lakes of various salinities (Great Salt Lake, Lake Clifton, Green Lake), in these examples “individual microbial clots are generally poorly defined” and “form an irregular, botryoidal-like, mesoscopic fabric that is unlike any of the fabrics observed by us in Lower Paleozoic thrombolites.” However, Moore and Burne (1994, pp. 23) considered that thrombolites in brackish to normal marine Lake Clifton, Western Australia, do closely resemble some early Palaeozoic examples in mesoclot shape and “the interframework of infilled fenestrae” and they pointed out that in Lake Clifton filamentous cyanobacteria (*Scytonema*) are important in thrombolite formation. Moore and Burne (1994, p. 21) noted that fine laminae, initially present in the Lake Clifton structures, are syndimentarily destroyed during mesoclot formation as carbonate precipitation continues, and also that the interframework fenestrae are intrinsic features “primarily related to the topography of the surface of the developing microbialite rather than to excavation of the structure by metazoan activity.” Great Salt Lake “algal mounds,” that consist of precipitated aragonitic framework and internal sediment (Halley, 1976, p. 439, Fig. 3), have a sub-centimetric thrombolitic fabric. Ferris et al. (1997)

suggested that thrombolitic fabrics in Kelly Lake, British Columbia, reflect a greater degree of calcification than in stromatolites.

Post-depositional thrombolites Aitken (1967, p. 1171) noted that thrombolite macroclots are prone to accentuation by recrystallization. This emphasizes a fundamental difference from stromatolites, whose laminae are essentially primary and not likely to be significantly enhanced by diagenesis. In contrast, clots could be significantly enhanced, e.g., by selective dolomitization, and in some cases secondarily produced, e.g., by bioturbation.

Stromatolites and thrombolites through time

Microbialite types are generally long ranging. Nonetheless, they show some distinctive differences in time distribution (Figure 11). Marine sparry crusts and hybrid stromatolites are typically Precambrian, and fine-grained stromatolites and thrombolites mainly range Neoproterozoic to the present day. Wrinkle structures show the longest range, whereas lithified coarse-grained carbonate thrombolites and stromatolites are only known from the past 10 Ma or less.

Archaean and Proterozoic

Stromatolites are relatively scarce in Archaean rocks until nearly the end of the eon. Their history begins with ~3.45 Ga coniform examples in the Pilbara region of Western Australia. These show fine continuous laminae (Lowe, 1980, 1983) and sparry microfabrics (Hofmann et al., 1999, Fig. 3). Their origins, and those of other Pilbara stromatolites, have been debated (e.g., Lowe, 1994, 1995; Buick et al., 1995), with recent studies supporting a biogenic origin (Hofmann et al., 1999, p. 1260–1261; Allwood et al., 2006, p. 717). Wrinkle and associated structures also suggest the presence of microbial mats in ~2,900 Ma siliclastic sediments of South Africa (Noffke et al., 2008), but these too are generally scarce. However, stromatolites are abundant in the ~2.55 Ga Campbellrand-Malmani carbonate platform of South Africa, locally forming elongate domes 10 m across and 40 m or more in length (Beukes, 1987, p. 9). In addition, these late Archaean carbonates contain distinctive “fenestrate microbialites” (Sumner and Grotzinger, 2004) consisting of millimetric to centimetric areas of light colored cement outlined by thin net-like layers (Figure 12). These have been interpreted as wispy convoluted microbial mats that were encrusted by calcite as they formed (Sumner, 1997a, b).

Large, often decametric, stromatolites are also conspicuous components of Proterozoic carbonate platforms (e.g., Grotzinger, 1986, p. 833; Petrov and Semikhatov, 2001, Fig. 6, p. 269). Where they are well preserved, they often show interlamination of sparry and micritic layers (e.g., Sami and James, 1996, p. 217). These dark-light layers that appear to represent alternations of lithified mat and abiogenic crust, are typical of “hybrid stromatolites” and are well seen in some *Conophyton* and *Baicalia* (Riding,

Microbialites, Stromatolites, and Thrombolites, Figure 11 Approximate time distributions of major categories of marine microbialites. Coarse agglutinated mats are mainly Neogene. Fine-grained mats and thrombolites are mainly Neoproterozoic and Phanerozoic. Marine “sparry” and “hybrid” crusts are mainly Archaean and Proterozoic. Wrinkle structures range Archaean to present-day. For some possible controls, see [Figure 14](#).

2008). Such incorporation of thin abiogenic sparry crusts appears to have contributed significantly to the size and relief of stromatolites throughout the Palaeo- and Mesoproterozoic. During the same period, extensive sheets of very small “microdigitate” stromatolites, typically <5 mm wide and <20 mm high (Hoffman, 1975, p. 262) were common in shallow peritidal environments (Figure 13). These “tufas” have been interpreted as essentially abiogenic (Grotzinger and Read, 1983).

An important control on Archaean-Proterozoic stromatolite formation was gradual decline in seawater carbonate saturation state (Grotzinger, 1989b; Grotzinger and Kasting, 1993). This progressively reduced stromatolite abundance (Grotzinger, 1990) and mediated a long-term trend from sparry crust to micritic carbonate sediments (Grotzinger and Kasting, 1993; Kah and Knoll, 1996). Transition to carbonate mud-dominated platforms ~1,400–1,300 Ma ago (Sherman et al., 2000) preceded the appearance of sheath-calcified cyanobacteria ~1,200 Ma ago (Kah and Riding, 2007). This significant transition, which led to Neoproterozoic development of calcimicrobial thrombolites (Aitken and Narbonne, 1989; Turner et al., 1993, 2000a, b), could reflect induction of CO₂-concentrating mechanisms (CCM) in cyanobacteria in response to fall in CO₂ levels below a threshold near ten times present-day levels (Riding, 2006) (Figure 14). CCMs are responses to reduced availability of inorganic carbon for photosynthesis, and in cyanobacteria include active bicarbonate uptake that

locally increases sheath pH, promoting calcification (Merz, 1992). Calcified filaments, such as *Girvanella*, altered microbial carbonate fabrics, disrupting stromatolite layering and promoting thrombolitic macro-clotted fabric. In subtidal environments, Neoproterozoic stromatolites are commonly interlayered with thrombolites with filamentous, clotted, and spongy “cellular” fabrics (Aitken and Narbonne, 1989) comparable with those of Cambro-Ordovician thrombolitic bioherms (Turner et al., 1993; 1997, p. 441, 449; 2000a, Figs. 6e, 8h and i).

Stromatolite decline

Stromatolites show long-term decline in abundance that may have commenced as early as the Palaeoproterozoic (Grotzinger, 1990) and is still observed in the Phanerozoic. Fischer (1965) suggested that decline since the Ordovician could reflect both reduction in carbonate saturation and competition by eukaryotes. Competition was subsequently emphasized when it appeared that marked late Proterozoic fall in stromatolite morphotypic diversity coincided with metazoan evolution (Awramik, 1971), but inception of decline prior to the appearance of metazoans implicates reduction in saturation state as the major influence (Grotzinger, 1990). It was also suggested that Cambrian thrombolites reflected disruption of stromatolites by burrowing organisms (Walter and Heys, 1985, pp. 150–151). However, Cambrian-Ordovician thrombolite fabrics are dominated by calcimicrobes that resist disruption (Kennard and James, 1986, p. 494) and

Microbialites, Stromatolites, and Thrombolites,
Figure 12 Fenestrate microbialite. Meshwork of large fenestrae (white) outlined by thin curved dark layers. Late Archaean Campbellrand-Malmani platform, South Africa. Width of field ~ 16 cm.

Microbialites, Stromatolites, and Thrombolites,
Figure 13 Microdigitate stromatolite, silicified after carbonate. Wumishan Formation, Mesoproterozoic, ~ 25 km north of Beijing, China. Width of view ~ 25 cm.

it has since been recognized that thrombolites appeared in the Neoproterozoic (Aitken and Narbonne, 1989), and possibly ~ 1.9 Ga in the Palaeoproterozoic (Kah and Grotzinger, 1992).

This leaves the question of the significance of trends in stromatolite diversity. Stromatolite shape reflects original

synoptic relief, determined by accretion rate relative to adjacent sediment (Figure 15). Low relative accretion rate results in low relief that makes stromatolites more prone to lateral incursion by sediment, thereby fostering complex shapes such as digitate forms (Figure 16). In contrast, high relative accretion rate results in high relief and simple shapes, such as domes and cones. Consequently, although mid-Proterozoic increase in morphotypic diversity, e.g., in branched stromatolites, has been regarded as a proxy for abundance, it more likely reflects low synoptic relief due to reduced relative accretion rate. Paradoxically, therefore, increased diversity could be sign that stromatolite growth was in decline due to reduced microbial growth and/or reduction in syndimentary lithification.

Snowball Earth

The prolonged warm Mesoproterozoic interval (Jenkins, 2003) was followed by Neoproterozoic (Sturtian, ~ 0.7 Ga Ma, Walter et al., 2000; Marinoan, ~ 0.635 Ga, Bodiselitsch et al., 2005) glaciations. Lower temperature and $p\text{CO}_2$ levels would have decreased seawater saturation state, hindering microbial calcification generally. Cooling would also have favored diffusive entry of CO_2 into cells and therefore may have slowed CCM development, further reducing cyanobacterial calcification. Nonetheless, microbialites are locally conspicuous in Cap Carbonates that immediately follow glacial deposits (e.g., Hoffman and Schrag, 2002; Corsetti and Grotzinger, 2005). Cap Carbonates have been suggested to reflect precipitation from seawater highly saturated for carbonate minerals as a result of alkaline upwelling and enhanced terrestrial weathering (Grotzinger and Knoll, 1995; Hoffman and Schrag, 2002). In the ~ 600 – 700 Ma Noonday Dolomite of California, narrow laterally amalgamated stromatolites define tubes of intervening detrital sediment fill (Figure 17). The overall organization of some Cambro-Ordovician *Favosamaceria* thrombolites (Shapiro and Awramik, 2006) resembles these “tubestones” (Corsetti and Grotzinger, 2005, p. 360).

Following Neoproterozoic “snowball” glaciations, global warming and O_2 rise could have reactivated CCM development, and rising temperature, calcium (Brennan et al., 2004), and $p\text{CO}_2$ (Berner and Kothavala, 2001) levels would have increased seawater saturation state, stimulating microbial calcification (Riding, 2006). This favored microbialite resurgence, and dendrolites, thrombolites, and stromatolites all became widespread in the early Cambrian (Rowland and Shapiro, 2002) (Figure 18).

Phanerozoic

Secular distribution

Both reefal microbial carbonates (Kiessling, 2002, Fig. 16) and calcified cyanobacteria (Arp et al., 2001) decline in abundance during the Phanerozoic, but this trend shows marked fluctuations. They are common in the late Cambrian-early Ordovician and late Devonian-early Mississippian, and scarce during the Cenozoic.

Microbialites, Stromatolites, and Thrombolites, Figure 14 Some secular trends and possible controls on microbial carbonate developments. Proterozoic stromatolite abundance (Grotzinger, 1990) and morphotypic diversity (Awramik and Sprinkle, 1999), together with Phanerozoic reefal microbial carbonate abundance (KieSSLing, 2002). These suggest overall long-term decline for at least the past 1,000 Ma. Reduction in both Sparry Crust and Hybrid stromatolites ~1,000 Ma ago may reflect decline in seawater carbonate saturation (Grotzinger, 1990). Stromatolite-like sparry crust occurs sporadically in the Phanerozoic, particularly in evaporite basins (Pope et al., 2000). Increase in thrombolites ~1,200–1,000 Ma ago could reflect development of cyanobacterial sheath calcification, reflecting inception of CO_2 -concentrating mechanisms (CCMs) as CO_2 levels declined to ~10 times present atmospheric level (PAL) (Riding, 2006). Inferred Proterozoic CO_2 trend based on Sheldon (2006), Kah and Riding (2007), Hyde et al. (2000) and Ridgwell et al. (2003). Phanerozoic CO_2 trend from Berner and Kothavala (2001, Fig. 13). Threshold for CCMs ($10 \times \text{PAL } \text{CO}_2$) based on Badger et al. (2002). Late Neogene inception of Coarse agglutinated stromatolites and thrombolite could in part reflect incorporation of diatoms into microbial mats and also generally low values of seawater carbonate saturation.

Fischer (1965) suggested that eukaryote competition and reduction in carbonate saturation state contributed to stromatolite decline from the Ordovician onward.

Carbonate saturation: Comparison with seawater saturation state for CaCO_3 minerals calculated from modeled seawater and CO_2 values shows broad positive correspondence with peaks of microbial/cyanobacterial carbonate abundance during much of the Palaeozoic and Mesozoic (Riding and Liang, 2005), supporting Fischer (1965). Lack of correspondence during the interval ~120–80 Ma ago (when calculated saturation ratio is high but microbial carbonate abundance was low) could reflect removal of carbonate deposition by pelagic plankton that significantly reduced actual saturation state.

Competition: The role of metazoan competition in late Proterozoic and early Palaeozoic stromatolite history is uncertain, and it is debatable whether metazoan grazing significantly affected stromatolite development (Pratt, 1982b) so long as carbonate saturation was high enough to ensure extensive early lithification of microbial mats. Nonetheless, it seems likely that from at least the mid-Ordovician onwards, overgrowth by skeletonized algae and invertebrates inhibited the formation of domical stromatolites and thrombolites. Subsumed within complex reef structures, microbial carbonates would instead have formed patchy and irregular crusts on and around skeletal organisms. Nonetheless, they were often important reef components (KieSSLing, 2002, Fig. 16).

Microbialites, Stromatolites, and Thrombolites,

Figure 15 Hypothetical interpretation of the significance of stromatolite shape. Shape is determined by synoptic relief that in turn reflects accretion rate of the stromatolite surface relative to adjacent sediment. In this view, enhanced stromatolite accretion generates high relief and simple shapes, such as columns, cones, and domes. In contrast, relatively low stromatolite accretion results in low relief. As a result, the stromatolite surface is prone to overlap by adjacent sediment, generating branching and irregular margins.

Microbialites, Stromatolites, and Thrombolites,

Figure 16 *Gymnosolen*, digitate stromatolite, Dalian, China, ~1.0 Ga.

Disaster biotas: The concept of stromatolite decline resulting from algal-metazoan diversification (Fischer, 1965; Garrett, 1970; Awramik, 1971) has also given rise to that of stromatolite resurgence in the aftermaths of mass extinctions (Schubert and Bottjer, 1992, p. 885). In this view, if metazoans can competitively exclude microbial carbonates then temporary reduction in metazoan abundance and diversity in the immediate aftermaths of mass

Microbialites, Stromatolites, and Thrombolites,

Figure 17 Laterally amalgamated columnar stromatolites (light color) separated by slightly darker tubular fills of detrital sediment. Noonday Dolomite, late Neoproterozoic, Mesquite Mountains, California, USA.

extinctions should permit temporary increase in microbial carbonates. Schubert and Bottjer (1992, 1995) interpreted early Triassic stromatolites as “post-mass extinction disaster forms.” However, whereas microbial carbonate reefal abundance also increased noticeably in the aftermath of late Devonian extinction, it did not increase following end-Ordovician, end-Triassic, and end-Cretaceous mass extinctions (Riding, 2006). Nonetheless, it is likely that in these situations, unconstrained by algal and invertebrate reef organisms, microbial mats were able to develop distinctive morphologies, and large domes, columns, and digitate structures have been reported, e.g., at the Permian-Triassic boundary in Sichuan, China (Kershaw et al., 1999).

Thrombolites: Flügel (2004, p. 378) suggested that thrombolite abundance also declined after the Cambrian, although they were still locally conspicuous, e.g., in the Silurian (Kahle, 2001), Devonian (Shapiro, 2000, p. 166), Mississippian (Webb, 1987, 2005), and near the Permian-Triassic transition (Kershaw et al., 1999; Ezaki et al., 2008). Thrombolites have been widely reported in the mid-late Jurassic (see Mesozoic-Cenozoic thrombolites, above), broadly coincident with the last major peak of abundance of calcified marine cyanobacteria (Arp et al., 2001, Fig. 3d).

Evaporite stromatolites: In addition to metazoan extinction, localized increase in carbonate saturation in evaporite basins will favor microbialite development. Pope et al. (2000, p. 1139) noted that isopachously laminated stromatolites, which they considered to be dominantly abiogenic, are well developed in association with major evaporite successions and cited examples in the Proterozoic and Phanerozoic, including the Silurian Michigan Basin of North America and the late Permian Zechstein Basin of northern Europe (Pope et al., 2000,

Figs. 7, 9). These conditions therefore marked temporary returns to conditions that promoted formation of the sparry and hybrid crusts typical of the Archaean and early Proterozoic.

Neogene coarse-grained thrombolitic stromatolites

Well-known present-day examples of columns and domes occur in wave- and current-swept environments at Shark Bay (Logan, 1961) and the Bahamas (Dravis, 1983; Dill

Microbialites, Stromatolites, and Thrombolites, Figure 18 Late Cambrian (Trempealeauan) thrombolite overlain by stromatolite, Smoky Member, Nopah Fm, Dry Mountain, California, north-western Death Valley National Park, USA. Pen ~15 cm long.

et al., 1986; Riding et al., 1991b; Reid et al., 2000). They accrete bioclastic and ooid sand, and have crudely layered (Logan, 1961) and thrombolitic (Aitken, 1967, p. 1171) fabrics. Several factors conspire in their formation: water movement, mat community, and seawater chemistry. High-energy grainy conditions facilitate trapping by lifting sand to the accreting mat surface, and simultaneously deter overgrowth by reefal encrusters (Dill et al., 1989, p. 10). At Shark Bay, seasonal hypersalinity also limits competitors. Together with rapid accretion this allows decimetric, and locally metric, columns to develop. Accretion is high because the mats are thick and soft, with abundant EPS (Decho et al., 2005). In addition to cyanobacteria, they contain diatoms and filamentous green algae that enhance trapping ability (Awramik and Riding, 1988; Riding et al., 1991b). The upper mat remains soft and sticky because it is largely uncalcified, and the early lithification necessary to support these large columns mainly occurs in, or below, the lower part of the mat. Microbial lithification by sulfate reduction (Visscher et al., 2000) is limited to very thin micritic crusts (Reid et al., 2000), cyanobacterial sheaths are uncalcified (Reid et al., 2000, p. 992), and calcification of algal filaments mainly occurs in cavities (Dravis, 1983; Whittle et al., 1993, p. 224). Formation of these coarse-grained thrombolitic stromatolites is therefore largely due to their thick, soft, EPS-rich mats. These in turn reflect a combination of Cenozoic circumstances: (i) seawater saturation state that is too low for cyanobacterial sheath impregnation, but permits early lithification and (ii) the presence of fast-growing microalgae, such as diatoms, which – from a geological standpoint – are relative newcomers to mat communities (Figure 14). Coarse-grained thrombolitic stromatolite domes and columns are well developed in the late Miocene of South-east Spain (Riding et al., 1991a; Braga et al., 1995; Feldmann and McKenzie, 1997) (Figure 19) but are not known in older rocks.

Microbialites, Stromatolites, and Thrombolites, Figure 19 Coarse-grained, oolitic, composite leiolite-stromatolite-thrombolite domes, late Miocene (Messinian), Joyazo, Almería, South-east Spain. Red pen, lower left, ~15 cm long.

Summary

During the Archaean and much of the Proterozoic, both microbial mat growth and abiogenic precipitation were involved in stromatolite development that, locally, was particularly abundant from the latest Archaean to early Neoproterozoic (Grotzinger and Knoll, 1999). The combination of these biogenic and abiogenic factors was responsible for the rapid growth that enabled stromatolites, ranging from extensive small microdigitate sheets (Grotzinger and Read, 1983) to decametric domes (e.g., Hofmann, 1998, pl. 8a), to dominate carbonate platforms for 1,500 million years. Well-preserved stromatolites with dark-light lamination (Sami and James, 1996; Petrov and Semikhov, 2001) suggest that lithified mat growth alternated with abiogenic sparry crust precipitation on a millimetric scale to form inter-layered hybrid crust stromatolites (Riding, 2008).

Decline in sparry crusts and hybrid stromatolites ~1,000 Ma ago probably largely reflects reduction in seawater saturation (Grotzinger, 1990). This change also broadly coincided with the inception of cyanobacterial sheath-calcification in the Mesoproterozoic. This important development may reflect induction of CO₂-concentrating mechanisms (CCM) to assist photosynthetic carbon uptake as CO₂ levels declined (Riding, 2006). It transformed microbialite fabrics, and calcified microbe thrombolites and stromatolites with filamentous fabrics were conspicuous in shallow subtidal environments until the early Ordovician. Subsequently, stromatolites and thrombolites were widely subsumed within algal-invertebrate reefs. In these closely packed habitats, they lacked space to develop classic dome and column morphologies, and instead mainly formed reefal crusts and irregular masses. Only where competitors were environmentally excluded, or absent (as in mass extinction aftermaths), did microbial domes briefly develop extensively.

Both competition and declining carbonate saturation limited the abundance of marine microbialites from the Ordovician onwards (Fischer, 1965), and they are much less widespread and abundant in the Cenozoic than in the Palaeozoic. But microbialite communities have the ability to reinvent themselves. Diatoms together with other microalgae have significantly enhanced mat trapping ability. In environments where reefal overgrowth is limited, and coarse grains abundant, these soft mats can create large coarse-grained columns, as at Shark Bay and Lee Stocking Island. Internally these have distinctive crudely layered thrombolitic stromatolite fabrics (Aitken, 1967); in external shape, they closely resemble some Palaeoproterozoic stromatolites.

Microbialites have changed significantly during their extraordinarily long history in shape, size, fabrics, and abundance. They have responded to microbial evolution, to environmental changes that have affected both carbonate sedimentation and microbial metabolism, and to the evolution of other organisms. To add to this complexity, whereas stromatolites are essentially lithified microbial mats, they may be intimately associated with abiogenic crusts.

Microbialites archive important geobiological changes in atmospheric composition, seawater chemistry, mat evolution, and biotic interaction. Their study continues to offer many challenges and opportunities.

MICROBIAL-METAL BINDING

Kurt O. Konhauser, David A. Fowle
 University of Alberta, Edmonton, Alberta, Canada

Definition

The accumulation of metal cations to microbes, largely through adsorptive processes to the outer cellular surfaces.

Overview

All bacteria have low isoelectric points (below pH 2 in most cases), and consequently, they interact with soluble metal cations and have them intimately associated with their surfaces (Harden and Harris, 1953). Considering their ubiquity in the near-surface environment and their characteristically large surface area-to-volume ratios, bacteria can have a significant influence on metal mobility and speciation in these settings.

Some bound metals (e.g., Ca and Mg) serve the purpose of stabilizing the negative charges of the anionic functional groups, and thus are relatively “fixed” into place, while other metals are much more exchangeable and provide a temporary positive charge to counter the negative charge induced by the deprotonation of the cell’s surface functional groups (Carstensen and Marquis, 1968). The strength of the metal–microbial bond is quantified by the surface complexation/binding constant (K_M), where M refers to the specific metal of interest. The greater its surface complex formation constant, the less likely

(e) association of SFF with or occurrence within SFF of other morphological bioforms such as fossil *Gallionella* or *Metallogenium*-like structures; (f) presence of vertically oriented elements (may resemble stalactites) resulting from mineral encrustation of filaments, filament strands, or mats while they are still flexible; and (g) inferred environmental conditions compatible with microbial growth, such as an abundant energy source and temperatures between ambient and $<120^{\circ}\text{C}$.

Types of organisms/substrates involved: The micro-morphology of SFF indicates that only filamentous micro-organisms are involved in their formation. Filamentous substrates of microbiological origin may include archaea, bacteria, and fungi. Some fabrics formed by encrustation of mineral fibers (these may be dissolved later) may show similar morphologies, but can usually be discriminated by evidence for characteristics typical of mineral fibers: Radial growth, variable fiber thickness, straight development, brittle behavior, and remnants of mineral fibers.

Conclusions

SFF represent a common, but often overlooked, type of biosignature from subsurface environments. SFF often display macroscopically visible fabrics that are easily recognizable and may be regarded as subsurface microbialites and the most conspicuous expression of the deep biosphere, representing in some ways an analog to stromatolites from surface environments. The very common occurrence in a wide variety of different rock types demonstrates that SFF are a common expression of subsurface life, wherever filamentous forms generate a large amount of biomass in relatively short time, allowing mineralization before organic filaments are destroyed. Organisms involved were chemolithotrophs (based on oxidation of Fe, S), but may also include heterotrophs living on chemolithotrophic primary producers. The formation in subsurface environments implies that no photosynthesizing organisms are involved. SFF-like features represent a target in the search for past life on Mars (Hofmann, 2007), as they might potentially be found in nearly all rock types.

SULFATE-REDUCING BACTERIA

Heribert Cypionka
 University of Oldenburg, Oldenburg, Germany

Synonyms

Dissimilatory sulfate reducers; Sulfate-reducing prokaryotes

Definition

Sulfate reducers are prokaryotic microorganisms (Archaea or Bacteria) that use sulfate as electron acceptor of an anaerobic respiration process.

Introduction

Sulfur is one of the essential elements for life. It makes about 1% of the dry mass of living organisms and is present in two amino acids, iron sulfur clusters, and some coenzymes. Several organisms can use sulfate as sulfur source and carry out assimilatory sulfate reduction, which yields sulfide groups of amino acids. In contrast, dissimilatory sulfate reducers release large amounts of hydrogen sulfide (H_2S and HS^-) as product of their energy metabolism and cause the characteristic smell of rotten eggs. The process is carried out by a heterogeneous group of bacteria and archaea that occur in anoxic environments with temperatures up to 105°C (Widdel, 1988; Castro et al., 2000). Due to the high sulfate concentration of seawater (28 mM), sulfate reduction is especially important in marine sediments but does also occur in many other anoxic environments, e.g., lake sediments, animal guts, etc.

Evolution

The capacity of dissimilatory sulfate reduction appears to be very ancient. Its antiquity can be derived from phylogenetic analyses as well as from the geologic record (Canfield and Raiswell, 1999; Shen and Buick, 2004). Near the root of the phylogenetic tree are numerous Archaea or Bacteria metabolizing sulfur species including prokaryotes living from dissimilatory elemental sulfur reduction, dissimilatory sulfate reduction, and anoxygenic photosynthesis. As in a mixture of different isotopes of the same element lighter species are (mass-dependent) preferably metabolized by enzymes, isotope analysis of sediments can give strong evidence for their biogenic origin. The sulfur isotope distribution (^{32}S , ^{34}S , and ^{36}S) in microscopic pyrites in the ~ 3.47 billion years (Ga) old North Pole barite deposit of northwestern Australia provides the oldest evidence of microbial sulfate reduction and the earliest indication of a specific microbial metabolism. Furthermore, the observation of non-mass-dependent sulfur isotope ratios in sedimentary rocks more than 2.45 Ga old and the disappearance of this signal in younger sediments is taken as one of the strongest lines of evidence for the transition from an anoxic to an oxic atmosphere around 2.45 Ga ago (Farquhar et al., 2007).

Phylogeny

More than 120 species of sulfate-reducing prokaryotes (SRP), belonging to four bacterial and two archaeal phyla are known today (Thauer et al., 2007). The largest group are (1) mesophilic delta-proteobacteria (e.g., *Desulfovibrio*, *Desulfobacter*, *Desulfobulbus*), the other groups are (2) thermophilic Gram-negative bacteria (*Thermodesulfovibrio*), (3) *Desulfobium*, a recently established thermophilic genus not closely related to other bacteria, (4) Gram-positive bacteria with the spore-forming genus *Desulfotomaculum*, (5) Euryarcheota with the hyperthermophile *Archaeoglobus*, and (6) Crenarcheota with the hyperthermophile *Caldivirga* (Itoh et al., 1999).

Physiological groups

The most important substrates utilized by SRP are fermentation products as H_2 , alcohols, and organic acids like acetate, propionate, and butyrate. While most sulfate reducers have a limited spectrum of substrates that support growth, new isolates have been obtained that metabolize a wide variety of compounds including hexadecane, toluene, and several types of substituted aromatics (Hansen, 1994). Physiologically, sulfate reducers can be separated in two groups: Representatives of the first group generally grow fast and oxidize organic substrates incompletely to acetate, while members of the second group, grow more slowly, but oxidize their substrates completely to CO_2 . An important electron donor oxidized with sulfate as terminal electron acceptor is methane. However, so far, it has not been clarified whether sulfate reducers can oxidize methane directly or if they receive reducing equivalents in another form from an archaeal partner.

Pathway of sulfate reduction

Sulfate reduction is a rather complicated process (Figure 1). First, the double-charged anion has to be taken up by specific transport systems. Then ATP is hydrolyzed to activate sulfate to adenosine phosphosulfate (APS). This is now reduced to (bi-)sulfite, which is reduced to sulfide by sulfite reductase. APS reductase and sulfite reductase are the key enzymes. The genes coding for them (*apr* and *dsr*) are often used in molecular studies to analyze phylogeny or community structures of sulfate-reducing SRP.

Reduction of sulfate with H_2 has a ΔG_0 of -151 kJ/mol of sulfate, which is about 1/6 of the value possible with oxygen as electron acceptor. Accordingly, there is not more than 1 ATP conserved per sulfate reduced.

Alternative electron acceptors

Most sulfate reducers can utilize other sulfur compounds than sulfate, often even with a better growth yield. Sulfite is an intermediate of sulfate reduction, but does not require an energy-dependent activation. Thiosulfate can be transformed to sulfide and sulfite in a single-step catalyzed thiosulfate reductase. Some sulfate reducers can also reduce elemental sulfur. Several sulfate reducers can utilize partially reduced compounds in the absence of an electron donor: Thiosulfate, sulfite, and elemental sulfur can be disproportionated to sulfate and sulfide, and the resulting (low amount of) free energy can be used for energy conservation (Bak and Cypionka, 1987).

Furthermore, some SRP can reduce nitrate or nitrite to ammonia, some can reduce metal ions as Fe^{3+} , Mn^{4+} or even U^{6+} (Lovley, 1993), some can reduce CO_2 to acetate (homoacetogenesis), and many can grow by fermentation of simple organic molecules like pyruvate.

Several SRB have been found to reduce molecular oxygen at high rates. The process is coupled to ATP conservation. However, it appears to be a defense mechanism. Sustainable growth of sulfate reducers with O_2 as electron acceptor has never been observed (Cypionka, 2000).

Sulfate-Reducing Bacteria, Figure 1 Steps of dissimilatory sulfate reduction and chemiosmotic energy conservation with H_2 as electron donor. Summary

Sulfate-reducing prokaryotes reduce sulfate to sulfide in an anaerobic respiration process. Sulfate reduction is ancient and found in Bacteria and Archaea. The main electron donors used by sulfate reducers are fermentation products. Sulfate reduction yields little energy and proceeds via several steps. Sulfate reducers are anaerobes, although some of them are able to reduce oxygen not coupled to growth. Alternatively, other sulfur compounds, nitrate or nitrite, and some oxidized metal ions can be used by some strains.

SULFIDE MINERAL OXIDATION

D. Kirk Nordstrom

U.S. Geological Survey, Boulder, CO, USA

Synonyms

Sulfide-mineral weathering; Sulfide-ore oxidation

Definition

Sulfide mineral. A metal-sulfide compound, such as pyrite (FeS_2), which forms at high temperature ($>50^\circ\text{C}$) in well-crystallized veins or masses and at low temperatures ($<50^\circ\text{C}$) in poorly crystalline and fine-grained particles.

Oxidation. The chemical process of reacting with oxygen. More generally, the chemical process of removing electrons from an atom or group of atoms.

Introduction

Metal-sulfide minerals are valuable as ores for metals that have a wide variety of uses from jewelry to components in vehicles and electronic equipment. They are found primarily in hydrothermal mineral deposits that occur in numerous geologic environments. The most common sulfide mineral is pyrite; other important sulfide ore minerals include chalcopyrite (copper ore), molybdenite (molybdenum ore), sphalerite (zinc ore), galena (lead ore), and cinnabar (mercury ore). When these minerals are exposed to weathering at the Earth's surface, either through natural processes or as a result of mining activities, they react with oxygen in air in the presence of water to form drainage that is frequently acidic and detrimental to the environment because of the high metal concentrations. The general term for this water is acid-rock drainage. When it originates from mining activities, it is called acid-mine drainage (Nordstrom and Alpers, 1999). Acid-rock drainage is produced by numerous chemical and microbiological processes within a complex hydrogeological environment. Extensive research has been employed to understand these processes, so that mine-site remediation can be more cost-effective and long-lasting. Weathering of sulfide minerals leads to natural enrichment in copper, gold, and silver in a process known as supergene enrichment. Copper dissolves in the infiltrating water and precipitates when it reaches unweathered sulfides downgradient, enriching the original sulfides. Gold and silver are highly insoluble and are enriched in the residual iron oxide cap or gossan that forms above the unweathered ore deposit. Sulfide-mineral oxidation from both mining and natural weathering is a major source of both dissolved sulfate and dissolved metals in natural waters.

Metal extraction of primary ores and of waste piles from previous mining activities is also accomplished by hydrometallurgical techniques that have optimized sulfide-mineral oxidation by increasing the temperature of leaching, adding catalytic reagents, and bioleaching by

adding microorganisms that are specially suited for increasing the rate of sulfide-mineral oxidation.

Chemolithotrophy

Acid-mine drainage has been known since the early days of mining by ancient civilizations and was documented by early Greek and Roman writers (Nordstrom, 2009). Oxidation of sulfide minerals by microorganisms, however, has a more recent history. Winogradsky (1888) recognized that microbes could actually derive metabolic energy from the oxidation of inorganic compounds. These microbes gain energy from the oxidation (or reduction) of inorganic compounds and acquire their carbon needs from the carbon dioxide in the air (autotrophy). Hence, many of them are chemolithoautotrophs or chemoautotrophs for short. During the first quarter of the twentieth century, it was suspected that microbes affected the oxidation of sulfide minerals, but it was not until Rudolfs and Helbronner (1922) demonstrated that microbes could oxidize zinc sulfide, and Colmer and Hinkle (1947) isolated *Thiobacillus ferrooxidans*, now *Acidithiobacillus ferrooxidans*, from acid-mine drainage that microbes were recognized to be important catalysts in the production of acid-mine drainage from sulfide-mineral oxidation.

Biogeochemistry

The overall reaction of a metal sulfide like pyrite with air and water can be represented by the equation:

Pyrite + oxygen + water $\rightarrow$ acid ferrous sulfate solution.

The acidity originates from the protons needed to balance out some of the loss of electrons from iron and sulfur oxidation. The dissolved ferrous iron further oxidizes to ferric iron:

Dissolved ferric iron easily hydrolyzes and precipitates as a colloidal phase, usually a mixture of fine-grained minerals, represented by either ferric hydroxide or commonly called hydrous ferric oxide (HFO):

Dissolved ferric iron is the oxidant that directly attacks the pyrite surface so that the more correct way to write the reaction would be:

Because dissolved ferrous iron oxidizes (Equation 2) much more slowly than the oxidation of pyrite by dissolved ferric iron (Equation 4), the oxidation of pyrite

would become negligible were it not for chemolithoautotrophic microorganisms. Many types of bacteria and archaea have been found to gain energy from the oxidation of ferrous iron and reduced sulfur in acidic environments (Norris, 1990; Nordstrom and Southam, 1997; Bond et al., 2000; Ehrlich, 2002). Some bacteria, such as *Acidithiobacillus ferrooxidans*, are capable of oxidizing both ferrous iron and reduced sulfur compounds (hydrogen sulfide, elemental sulfur, thiosulfate, and tetrathionate). Other bacteria, such as *Leptospirillum ferrooxidans*, are only able to oxidize ferrous iron and some bacteria, such as *Acidithiobacillus thiooxidans*, are only capable of oxidizing reduced sulfur compounds. Iron-oxidizing archaea include *Acidianus brierleyi*, *Sulfolobus acidocaldarius* (Nordstrom and Southam, 1997), *Ferroplasma acidiphilum* (Golyshina et al., 2000), and *Ferroplasma acidarmanus* (Edwards et al., 2000). Although *Acidithiobacillus ferrooxidans* has been the subject of more studies, *Leptospirillum ferrooxidans* seems to be the more common species in acid-mine drainage (Rawlings et al., 1999; Bond et al., 2000).

The geochemistry of sulfide-mineral oxidation and its effect on surface-water quality can vary substantially depending on the composition and grain size of the sulfide minerals. Common sulfide minerals are usually either disulfides like pyrite (FeS_2) and molybdenite (MoS_2) or monosulfides like sphalerite (ZnS) and galena (PbS). Molybdenite is hydrophobic and rather insoluble so that it oxidizes and weathers very slowly whereas sphalerite is more soluble and readily reacts with acid water to produce

hydrogen-sulfide gas. The grain size of these minerals can greatly affect their oxidation and dissolution rate. The smaller the grain size, the faster they react. Hence, fine-grained crystals of pyrite can react more quickly than large crystals of sphalerite even though sphalerite would dissolve more quickly if it were the same grain size as pyrite. Marcasite has the same composition as pyrite but it reacts more rapidly because it has a different crystal structure that is more amenable to oxidative weathering.

As acid-mine drainage mixes with surface waters, the dissolved ferrous iron oxidizes and precipitates to hydrous ferric oxide (HFO) which is an excellent sorbent for trace metals. Consequently, some of the dissolved copper, lead, zinc, arsenic, and other metals will be sorbed onto colloidal particles of HFO and decrease the potential toxicity, one of several processes known as natural attenuation. This process is enhanced by the growth of masses of bacteria and algae which also sorb some of the metals, removing them from solution and decreasing the concentration transported further downstream.

Environmental consequences of sulfide mineral oxidation

Acid-mine drainage from sulfide-mineral oxidation usually discharges into streams, rivers, and lakes (Figure 1). The pH values of acid-mine drainage range from 1 to 4 although values as low as -3.5 have been measured (Nordstrom et al., 2000). The high concentrations of metals such as copper, chromium, zinc, lead, cadmium,

Sulfide Mineral Oxidation, Figure 1 Effluent from the Tinto and Santa Rosa mines flowing into the Villar River, Spain. (Photograph courtesy of Manuel Caraballo Monge, Barcelona, Spain.)

mercury, manganese, iron, and aluminum found in acid-mine drainage is too toxic for invertebrates, amphibians, fish, and other forms of aquatic or terrestrial life. Only bacteria, algae, and fungi seem to survive when the pH is about 3 or less and the concentration of metals is a few hundred parts per billion or higher. Occasionally cyanide is also released into surface waters from gold processing with harmful effects. Releases of acid-mine drainage have caused the loss of enormous quantities of fish as well as harming livestock, mammalian wildlife, and crops. Two of the largest reported spills destroyed temporarily the biological habitat of two separate river systems. One spill was from the Aznalcollar impoundment in southern Spain in April, 1998, discharging 6 million cubic meters of acid water and pyritic fines into the Guadiamar River and ruining thousands of hectares of farmland. The other spill occurred in January, 2000, releasing a hundred thousand cubic meters of cyanide and heavy metals from a 4 km impoundment at the Aurul gold extraction plant near Baia Mare in northwestern Romania. The cyanide-rich water moved down to the Lapus River, then to the Tisza River, and finally to the Danube River all the way to the Black Sea. Smaller spills from the same region occurred again over the next 2 months. Approximately, 1,200 t of fish were killed from this spill, bird life was affected, thousands of fishermen were out of work, and water supplies for several towns and rural communities were badly contaminated.

Treatment technology

Innumerable ideas have been suggested for alleviating the harmful effects of sulfide-mineral oxidation and acid-mine drainage production. These suggestions include passive wetlands treatment, bioreactors, electrochemical treatment, exchange resins, reverse osmosis, and the use of various biosolids. However, the most commonly used, safe, and cost-effective treatments today are lime–lime-stone neutralization and precipitation of the metal-rich sludge in settling ponds combined with water-management techniques. An important engineering aspect is the construction of containment structures for hazardous materials that can withstand intense rainstorms and floods and that will prevent releases into surface-water and groundwater supplies.

Conclusion

Sulfide-mineral oxidation is a complex hydrobiogeochemical process involving the oxidation of metal-sulfide minerals, catalyzed by numerous bacterial and archaeal microbial species, and producing acid-rock drainage. Mining activities enhance the rate of this process, causing the production of acidic metal-rich drainage that make receiving streams, lakes, and rivers unfit for general usage and injurious to aquatic and terrestrial biota. Major spills of mine wastes into receiving waters have severely damaged valuable aquatic resources,

farmland, community water supplies, and the economic stability of those who depend on farming and fishing. Much effort has gone into the remediation of old inactive mines and current mining activities to improve water quality for beneficial uses but the scale and complexity of the problem continues to challenge engineers and regulators.

SULFUR CYCLE

Michael E. Böttcher

Leibniz Institute for Baltic Sea Research, Warnemünde, Germany

Synonyms

Biogeochemical sulfur cycle; Sulfate reduction and sulfide oxidation; Transformation of sulfur compounds

Definition

Sulfur. Chemical element that is one of the constituents of the Earth's compartments and living organisms. While the average sulfur content of the whole Earth is about 2%, the crust contains only about 0.07% sulfur (Brimblecombe, 2003).

Sulfur cycle. Biogeochemical system of biotic and abiotic transformations of inorganic and organic sulfur-bearing components, in and between, the lithosphere, hydrosphere, atmosphere, and biosphere. Sulfur initially enters the biogeochemical cycle via volcanic activity and continental erosion. Today, the modern sulfur cycle is influenced by human activity. The Earth sulfur reservoir is assumed to have been essentially constant through time (Garrels and Lerman, 1984).

Assimilative sulfate reduction. Sulfate (SO_4^{2-}) is reduced to organic R-SH groups by plants, algae, and fungi.

Dissimilative sulfur and sulfate reduction. Hydrogen sulfide (H_2S) is produced from elemental sulfur (S^0) or dissolved sulfate by sulfur- and sulfate-reducing microorganisms, respectively. For sulfate reduction coupled to the oxidation of marine organic matter or methane, the overall reactions are:

Desulfuration. Hydrogen sulfide is produced from sulfur-containing organic molecules.

Oxidation of hydrogen sulfide. Production of sulfur intermediates, elemental sulfur, thiosulfate ($\text{S}_2\text{O}_3^{2-}$), sulfite (SO_3^{2-}), and/or sulfate by bacterial or abiotic oxidation (Jørgensen and Nelson, 2004). Possible reactions are:

Oxidation of sulfur. Sulfate is generated by the oxidation of elemental sulfur. A possible reaction is (gradient bacterium *Thioploca*):

Disproportionation of sulfur intermediates. Sulfate and hydrogen sulfide are produced by the low-temperature bacterial metabolism of sulfur intermediates. The stoichiometries of the reactions are (Finster, 2008):

In the presence of oxy(hydroxi)des of iron(III) or manganese (IV) the following stoichiometries are obtained (Böttcher and Thamdrup, 2001; Finster, 2008):

Hydrolysis of elemental sulfur. Sulfate and hydrogen sulfide can be produced by the abiotic hydrolysis of elemental sulfur at high temperatures (Smith, 2000), according to:

Formation of iron disulfide (pyrite). The low-temperature formation of iron disulfide typically takes place via the polysulfide ($\text{S}^{\circ*}$) or hydrogen sulfide pathway by the reaction with the precursor iron monosulfide (Rickard and Luther III, 2007):

The degree of pyritization (DOP) indicates the relative amount of reactive sedimentary iron that has already been reacted to pyrite.

The global sulfur cycle

The global reduced and oxidized reservoirs of sulfur, carbon, oxygen, and selected metals are coupled on different scales via redox-driven chemical, biological, and geological processes (Figures 1–4). Parts of this cycling, as the reaction between sulfuric acid (that later became popular in industrialized times as “acid rain”) and carbonate rocks, were already described in the nineteenth century by Johann Wolfgang von Goethe (Figure 1) in his famous novel “Elective affinities” (German: “Wahlverwandschaften”; published in 1809).

On Earth, pure sulfur occurs in elemental form as for example in volcanic regions, and the quantitative use of sulfur-bearing compounds by man has been used as a proxy for economic wealth (Brimblecombe, 2003). Iron sulfide sulfur occurs in almost all types of rocks and sediments and is even found in extraterrestrial meteorites. In sediments that are not under the influence of hydrothermal activity, the occurrence of sulfide sulfur is indicative for the activity of sulfate-reducing bacteria

"... Thus what we call limestone is a more or less pure calcareous earth in combination with a delicate acid, which is familiar to us in the form of a gas. Now, if we place a piece of this stone in diluted sulphuric acid, this will place a possession of the lime, and appear with it in the form of gypsum, the gaseous acid at the same time going off in vapour. Here is a case of separation; a combination arises, and we believe ourselves now justified in applying to it the words 'Elective Affinity;' it really looks as if one relation had been deliberately chosen in preference to another...."

Johann Wolfgang von Goethe 'Elective Affinity'
(German: *Wahlverwandtschaften*)

Sulfur Cycle, Figure 1 Coupling of the sulfur and carbon cycles according to Johann Wolfgang von Goethe. (Translation from Niles, 1872.)

Sulfur Cycle, Figure 2 Mass balance model of coupling between the young and old global carbon and sulfur reservoirs. (Redrawn from Berner, 1987, as a modification of the model by Garrels and Lerman, 1984.)

(e.g., Jørgensen and Kasten, 2006). Whereas sulfur is assimilated by living organisms where it is bound to, for instance, amino acids, most of the organic sulfur found in sediments is derived from early diagenetic reaction of organic matter with reduced and intermediate sulfur species (Sinninghe Damsté and de Leeuw, 1990). The decomposition of organic matter in the presence of sulfate is catalyzed by microorganisms that gain energy from the dissimilatory reduction of sulfate (e.g., *Desulfovibrio* and *Desulfobacter*; Rabus et al., 2001). Microbial oxidation of sulfide (e.g., by green and purple sulfur bacteria; gradient bacteria as *Beggiatoa* or *Thioploca*; Jørgensen

and Nelson, 2004), disproportionation (e.g., *Desulfovibrio*, *Desulfocapsa*, Finster, 2008), or further oxidation of sulfur intermediates (e.g., *Thiobacillus*) can take place aerobically or anaerobically. In the aquatic low-temperature environment, dissolved and metal-bound sulfide may also be abiotically oxidized, e.g., by manganese dioxide (Jørgensen and Nelson, 2004). The lowest oxidation state of sulfur is $-II$ (e.g., in hydrogen sulfide). In its highest oxidation state $+VI$ (e.g., in sulfate), sulfur is bound to oxygen and found as (biogenic or abiotic) barite or evaporitic sulfate minerals (e.g., gypsum or anhydrite).

Sulfur in the Atmosphere

The first atmospheric sulfur components on Earth (mainly SO_2 and H_2S) were derived from volcanic activity and may have led to the first acid rain on Earth (Farquhar et al., 2000). Volcanoes still contribute to the atmospheric sulfur budget, besides emissions from the oceans (e.g., dimethyl sulfide (DMS), carbon disulfide), coastal and wetland areas. Most of the different components temporarily end as sulfate. The anthropogenic combustion of sulfur-bearing fossil fuels in the past century not only produced CO_2 , but also led to the formation of sulfuric acid ("acid rain"), which partly led to increased rock weathering that again linked the carbon and sulfur cycles (Figure 1). In the ongoing discussion of dealing with climate change, the observations from the eruption of Mount Pinatubo are taken as an event-type base for geo-engineering concepts to decrease the global surface temperature by the artificial release of sulfur components into the stratosphere (Crutzen, 2006).

Sulfur in surface and groundwaters, and freshwater sediments

Rainwater sulfate, sulfur dioxide, and organic sulfur enter the water-unsaturated soil zone, where further

transformations take place. Geological contributions from soil and aquifer minerals vary strongly and may include gypsum dissolution and metal sulfide oxidation. Near-surface oxidation of pyrite from coal-mining activities leads today to the anthropogenically induced phenomenon of “acid mine drainage” (Holmer and Storkholm, 2001). Sulfur cycling in freshwater lake sediments associated with organic matter diagenesis is controlled by a number of factors, including temperature, light conditions, the availability of sulfate, organic matter, electron acceptors and nutrients, and macro faunal abundance (Holmer and Storkholm, 2001). Groundwater may play an important role in influencing sulfur cycling, for instance, via the

supply of evaporite-derived sulfate (Swiss Lago di Cadagno, as an example) and rock weathering (Böttcher, 1999). Sulfur cycling via organic sulfur compounds (Figure 4) plays an important role in freshwater sediments and soils (Mitchell et al., 1992; Holmer and Storkholm, 2001). Finally, sulfate may reach the ocean where further processing takes place (Figure 4).

Sulfur Cycle, Figure 3 Major reservoirs and burdens of sulfur in Tg. (Modified after Brimblecombe, 2003.)

Sulfur Cycle, Figure 6 *Upper part:* Box model for the global sulfur cycle (after: Canfield, 2004). *Lower part:* Variation of the stable sulfur isotope composition of sedimentary sulfides and coexisting seawater sulfate (from evaporites and barite). (After data from Canfield and Teske, 1996, with additions by Böttcher, unpublished data, 1998–2000.)

Sulfur in seawater and marine sediments

With a residence time of at least 8 million years, dissolved sulfate in seawater is well-mixed and reflects changes in the fluxes between and sizes of the major reservoirs (Figures 2 and 6). Whereas at mid-oceanic ridges, chemical sulfate reduction occurs in heated seawater that circulates through the Earth's crust, the low temperature dissimilatory sulfate reduction is linked to the enzymatic activity of sulfate-reducing bacteria which requires the abundance of metabolizable dissolved organic carbon compounds or methane (Jørgensen and Kasten, 2006). The anaerobic oxidation of methane associated with microbial reduction of sulfate is an important trap to prevent methane from escaping into the water column (Jørgensen and Kasten, 2006). In continental margin sediments, microbial sulfate reduction accounts for up to more than 50% of the organic matter oxidation (Skyring, 1987; Jørgensen and Kasten, 2006). Sulfate reduction may also take place in anoxic water columns (e.g., Black Sea). Most of the biogenic sulfide is reoxidized at the benthic or pelagic redoxclines by microbial or chemical processes (Jørgensen and Nelson, 2004) leading to the

metastable formation of intermediate sulfur species, or finally sulfate. The sulfur intermediates can be further oxidized, reduced, or disproportionated (Figure 4). Only a small portion of sulfide is finally buried as iron sulfides (essentially pyrite; Figure 5) or organic sulfur (Figures 2 and 4).

A number of external factors may directly or indirectly influence the rates of microbial sulfate reduction and sulfide burial efficiency, on different scales that can be reflected by the contents of sedimentary sulfur and the “reservoir” effect reflected in overall isotope discrimination (Figure 7).

Geochemical tracers for sulfur cycling: Stable sulfur and oxygen isotopes

Fractionation of stable sulfur (in dissolved and solid phase sulfur) and oxygen isotopes (in sulfate and sulfate-bearing minerals) takes place via biological and abiotic transformations and leads to isotope signatures that can be used to identify sources and biological, chemical, and physical processes involved (Canfield and Raiswell, 1999; Böttcher, 2010). Oxygen isotope fractionation can be used

Sulfur Cycle, Figure 7 Compilation of potential factors influencing availability of oxidizable organic matter available to sulfate-reducing bacteria and consequences for sulfate reduction rates and associated kinetic and reservoir size-induced sulfur isotope effect. (Modified after Ohmoto, 1992.)

to trace sulfate sources in aerobic environments (Clark and Fritz, 1997). The composition of dissolved sulfate and sedimentary diagenetic barite after modification by microbial sulfate, on the other hand, is finally governed by intracellular oxygen isotope exchange toward equilibration with surrounding water (Wortmann et al., 2007). The fossil sedimentary isotope record of pyrite (Figure 6) and anhydrite/barite/carbonate-bound sulfur, reflects the coupled changes in the atmospheric composition, the biogeochemistry of the sedimentary sulfur cycle and the fluxes between the different sulfur-bearing reservoirs (Figures 1–4 and 6) (e.g., Berner, 1987; Canfield and Teske, 1996; Canfield and Raiswell, 1999; Canfield, 2004).

Conclusion

The sulfur cycle is of general importance due to its involvement in the anaerobic mineralization of organic matter, and therefore, tight coupling to the carbon cycle. Its geochemical signature in sediments provides hints for identification of key processes associated with the evolution of life and the atmosphere on Earth. Some of the many open questions pertaining to the (bio)geochemistry and geomicrobiology of sulfur are (1) the importance of microbial versus chemical sulfide oxidation, (2) the quantitative importance of metastable intermediate and reduced sulfur species in the low-temperature sulfur cycle (Rickard and Morse, 2005; Finster, 2008), (3) the quantitative role of sulfur cycling for the deep biosphere (Jørgensen and D'Hondt, 2006), and (4) the role of metal

sulfides in extreme environments on the pre-biotic Earth for the later development of the precursors of life (Rickard and Luther III, 2007).

SULFUR ISOTOPES

Michael E. Böttcher
 Leibniz Institute for Baltic Sea Research, Warnemünde,
 Germany

Synonyms

Radioactive sulfur isotopes; Stable sulfur isotopes

Definition

Sulfur. A chemical element that is one of the constituents of living organisms and of the Earth.

Isotopes. Isotopes are different nuclear forms of the same element. For a given element, a constant number of protons but different numbers of neutrons in the nucleus correspond to different isotopes. Sulfur of standard atomic mass 32.065 u has 18 isotopes, most of which are not stable and undergo radioactive decay.

Stable sulfur isotopes. Stable isotopes are isotopes that do not decay within an experimentally observable time frame. Stable isotopes have essentially the same chemical characteristics and, therefore, their behavior is chemically almost identical. The different masses lead to isotope fractionation in chemical, physical, and especially biological reactions. Four stable isotopes occur in nature: ^{32}S (95.02%), ^{33}S (0.75%), ^{34}S (4.21%), and ^{36}S (0.02%) (Hoefs, 2008). Typically, the ratio of the two most

abundant sulfur isotopes is measured and presented in the conventional δ notation as opposed to the Vienna-Canyon-Diablo-Troilite (V-CDT) standard ($\delta^{34}\text{S}$ values per mil versus the V-CDT standard). In aerobic surface environments, the sulfur isotopic composition of sulfate is often used for source identification (e.g., anthropogenic versus geogenic sulfate in rain, river, and ground waters (e.g., Clark and Fritz, 1997). Only recently has the fractionation of the minor isotopes ^{33}S and ^{36}S also been introduced into sulfur isotope biogeochemistry (e.g., Farquhar et al., 2003).

Radioactive sulfur isotopes. Sulfur has 14 unstable isotopes. Radioactive sulfur with mass 35 is formed in the atmosphere from cosmic ray spallation of argon with mass 40 and has a half-life of 87 days. Therefore, it is used in hydrological studies of biologically less active surface environments. ^{35}S -labeled sulfur compounds are used in experiments to determine microbial and chemical sulfur turnover, upon microbial dissimilatory sulfate reduction, for instance (e.g., Kallmeyer et al., 2004). The other radioactive sulfur isotopes are all short-lived.

Fractionation of stable sulfur isotopes

Sulfur isotopes are fractionated upon microbial and abiotic sulfur transformations and the isotope signal may be preserved in sedimentary sulfide- and sulfate-bearing solids, organic matter, and to a minor extent, elemental sulfur (e.g., Canfield, 2001; Amend et al., 2004). The majority of geochemical and microbial studies on sulfur isotopes have so far focused on the fractionation of ^{32}S to ^{34}S . The most important isotope discrimination step occurs during dissimilatory reduction of dissolved sulfate within the bacterial cell. The overall change in the valence state of sulfur by pure cultures leads to hydrogen sulfide that is enriched in the lighter isotope by up to about 50 per mil when compared to sulfate (Figure 1). The magnitude of isotope discrimination depends on conditions such as cellular sulfate reduction rate, substrate and sulfate concentrations, and the organisms (e.g., Kaplan and Rittenberg, 1964; Chambers and Trudinger, 1979; Bolliger et al., 2001; Canfield, 2001; Amend et al., 2004). A maximum fractionation upon sulfate reduction of up to about 70 per mil is obtained from pore water modeling in natural environments (e.g., Wortmann et al., 2001), which is close to the value predicted for thermodynamic equilibrium conditions. Further partial or complete oxidation of hydrogen sulfide is associated with only small isotope discrimination, but may lead to the formation of (metastable) sulfur intermediates. The bacterial disproportionation of these compounds (e.g., elemental sulfur, thiosulfate, sulfite) yields hydrogen sulfide that is further enriched in the lighter isotope compared with the original sulfide (Figure 1).

This may contribute to the magnitude of isotope partitioning found in shallow natural environments and the fossil record (Canfield, 2001).

shortly after the extreme glaciations during the late Neoproterozoic (Hoffman et al., 1998) and was nearly synchronous with the rapid evolutionary pulse that coincides with the Ediacaran and Cambrian radiations. Final assembly of Gondwanaland and a circum-Gondwanaland mountain chain is thought to have provided nutrients to the oceanic realm and also resulted in a large $^{87}\text{Sr}/^{86}\text{Sr}$ spike due to the erosion of the mountains (Squire et al., 2006). Therefore, links between the assembly of the Gondwanaland supercontinent and biological evolution are forwarded by numerous studies (Meert and Lieberman, 2008).

GREAT OXYGENATION EVENT (GOE)

The term “Great Oxygenation Event” (GOE, also known as “Great Oxidation Event,” “oxygen catastrophe,” or “oxygen crisis”) describes a critical environmental change in Earth history that resulted from the appearance of diatomic oxygen (O_2), a waste product of oxygenic photosynthesis, in the atmosphere. The GOE occurred around 2.4 billion years (Ga) before present, close to the boundary between the Archean and the Proterozoic (2.5 Ga). For details, please refer to “[Critical Intervals in Earth History](#).”

GREEN ALGAE

Green algae are photosynthetic eukaryotes with simple plastids (derived from primary endosymbiosis) that are mostly microscopic and rarely more than a meter in greatest dimension. The approximate 6,000 extant species show an enormous diversity of growth habit and fine details of their cellular architecture. Green algae occur as unicellular or colonial, microscopic or macroscopic, motile planktonic, as well as benthic attached forms. Some (e.g., Dasycladales) are important carbonate producers in aquatic environments, others live in symbiotic associations with fungi to form lichens in terrestrial settings. Green algae living as endosymbionts inside heterotrophic organisms are a common phenomenon. The order Charales, in which full tissue differentiation occurs, is considered to include the closest relative of higher plants. For details, please refer to entry “[Algae \(Eukaryotic\)](#).”

THIOESTER WORLD

Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

Christian de Duve (1991, 1994, 1995) proposed a Hadean “Thioester World” which should have preceded the succeeding RNA world. Thioester molecules were probably very common in the proposed “primordial organic soup”. Thioesters are formed when a ‘thiol’ joins a carboxylic acid (R'–COOH) under acidic and high temperature environmental conditions. The general form is written as an organic group (R) bonded with sulfur and hydrogen, hence R-SH. H₂O is released in this process, and forms finally a thioester: R–S–CO–R'. The “Thioester World” represents a hypothetical very early stage in the origin of life that could have provided the energetic and catalytic framework of a protometabolic set of primitive chemical reactions, like in the transaction of molecular groups, and in Redox-reactions. Thioesters were probably involved in the formation of energy-rich phosphates via acylphosphates and pyrophosphates as precursor compounds. The thioester bond is a high-energy bond and probably thioesters had the same function as ATP as an energy supplier. With the help of thioesters amino acids (AS) could also spontaneously polymerise and form first simple proteins. The “primordial organic soup” was enriched with AS may be provided by carbonaceous chondrites and comets which collided with the early earth and the early earth was also characterized by an intense volcanic activity. This volcanic activity generated H₂S and thiols are expected to arise readily in these H₂S-rich fluids. In laboratory experiments, imitating the Hadean conditions on Earth, it was possible to obtain cysteamine, b-alanine and pantonic acid known as ‘pantetheine’ which is a precursor of coenzyme A (Keefe et al., 1995). The thioester world is an important hypothesis in the understanding of early life processes which may explain essential reactions expected in the prebiotic world.

Definition

Colorless, sulfur and nitrate storing bacterium belonging to the gammaproteobacteria, spherical, vacuolated.

Thiomargarita namibiensis, the largest known prokaryote, was first discovered in 1997 off the coast of Namibia and called the Namibian sulfur pearl. Together with the larger species of the genera *Beggiatoa* and *Thioploca*, they belong to a group of benthic bacteria that live by the oxidation of sulfide to sulfate with internally stored nitrate. Sulfide is first oxidized to sulfur, which can be stored by the bacteria as an energy reservoir. Nitrate is accumulated to very high concentrations (up to 800 mM) in a central vacuole, which comprises most of the cell volume. The single spherical cells are 100–300 µm in diameter and are held together in a chain by a mucus sheath ([Figure 1](#)). A new species of *Thiomargarita*, which was discovered in the Gulf of Mexico, appears as single cells without a slime sheath and can perform reductive divisions in up to three planes. These *Thiomargarita* cells resemble some of the fossils from the Doushantuo Formation in China, which have been classified as the oldest metazoan eggs and embryos.

Thiomargarita namibiensis inhabits the upper centimeters of fluid, sulfidic diatom ooze, which forms the sediment off the Namibian coast. Because of their large size, they can store enough nitrate to survive many years within the sulfidic sediment without getting into contact with nitrate from the open water. As *Thiomargarita* cells are not motile, they have to get suspended with their sediment, in order to refill the vacuole with nitrate. Off Namibia sediment resuspension may occur via frequent methane eruptions. Apart from sulfur and nitrate *Thiomargarita* cells

Thiomargarita, Figure 1 A chain of *Thiomargarita* cells (three cells visible) seen with a stereo microscope on a black background and illuminated from the side. The cells with a diameter of about 0.2 mm are held together by a mucus sheath. To the left there is part of an empty slime pocket visible. The large sulfur inclusions can be seen as shining white globules.

can also store polyphosphate, which they may release periodically resulting in high phosphate concentrations around the cells and spontaneous precipitation of phosphorus rich minerals.

Bacteria living of sulfur compounds.

Introduction

The term thiotrophic is derived from Greek and translates to sulfur nourishment, meaning that thiotrophic bacteria live on sulfide or other reduced sulfur compounds. Traditionally, these bacteria are often called sulfur bacteria because some of them can be recognized as sulfide oxidizers in the microscope, as they store elemental sulfur within the cells or excrete elemental sulfur into the medium. Microbiologists distinguish between colorless sulfur bacteria and green and purple sulfur bacteria, the latter two being phototrophs, which use sulfide as electron donor for anoxygenic photosynthesis (Robertson and Kuenen, 2006). The purple and green sulfur bacteria are generally not called thiotrophic because they gain energy by photosynthesis and are thus classified as phototrophic, even though sulfide is required for this process. Free-living, sulfide oxidizing bacteria are, out of tradition, still called sulfur bacteria rather than thiotrophic bacteria. A large group of sulfide oxidizing bacteria lives in symbiotic association with higher organisms (Cavanaugh et al., 2006). These symbionts are generally called thiotrophic in order to distinguish them from the methanotrophic symbionts, which gain energy by the oxidation of methane. In general, the ability to live by the oxidation of reduced sulfur components is widespread among eubacteria and even archaea, but a large number of thiotrophic bacteria are found within the gammaproteobacteria (Sievert et al., 2007).

Sulfide (the sum of H_2S , HS^- , and S^{2-}) is a difficult energy source because it is toxic for respiratory processes, as it tends to bind iron. Therefore, even thiotrophic bacteria have to prevent very high sulfide concentrations. Microbiologists often avoid this problem by offering thiosulfate ($\text{S}_2\text{O}_3^{2-}$) instead of sulfide for cultivating thiotrophic bacteria. Most thiotrophs oxidize sulfide with oxygen. This reaction also occurs abiotically, but at much lower rates, so thiotrophic bacteria usually compete successfully with the chemical oxidation of sulfide to sulfur in the presence of oxygen. Thiotrophs mostly oxidize sulfide completely to sulfate, to gain the maximum of energy, but some thiotrophs excrete or internally accumulate the intermediate elemental sulfur. Other major intermediates of sulfide oxidation are thiosulfate, tetrathionate, and sulfite.

The oxidation of sulfide with nitrate instead of oxygen is an energy releasing reaction, which is used by some thiotrophic bacteria. One group of free-living sulfur bacteria is even a specialist on nitrate respiration, by possessing a large vacuole in which nitrate is stored in almost molar concentrations. Apart from the oxidation of reduced sulfur compounds bacteria can also gain energy by disproportionating thiosulfate or sulfur to sulfide and sulfate. This inorganic fermentation of thiosulfate or sulfur seems to

be a widespread process both in marine and in freshwater sediments (Jørgensen and Bak, 1991).

Sulfidic environments

A major source of sulfide in the marine environment is the anaerobic degradation of organic materials by sulfate-reducing bacteria. Consequently, high sulfide concentrations and dense populations of thiotrophic bacteria occur in areas where a lot of organic materials settle at the sea floor, as for example in upwelling areas, in eutrophic coastal environments or at whale falls. The main source of sulfide is the sediment; only in very enclosed eutrophic basins sulfide may be produced in the open water (e.g., the Black Sea). Another source of sulfide is highly reduced fluids, which are transported to the sediment surface by advection (e.g., hydrothermal vents, seeps). These are point sources of sulfide in the ocean, which can be densely populated by free-living or symbiotic, thiotrophic bacteria.

Free-living thiotrophs

Many heterotrophic bacteria are capable of also oxidizing reduced sulfur components for energy generation and many thiotrophic bacteria can also use organic carbon as substrate for growth (Robertson and Kuenen, 2006). The classical lithoautotrophic sulfide-oxidizing bacteria are the thiobacilli, which have recently been reclassified and are now distributed to several different genera (e.g., *Acidithiobacillus*, *Halothiobacillus*). Another classical and well-studied group of thiotrophic bacteria are the members of the genus *Thiomicrospira*. Both groups harbor strains which can use nitrate as alternative electron acceptor with nitrogen as the end product (*Thiobacillus denitrificans* and *Thiomicrospira denitrificans*, now *Sulfurimonas denitrificans*). It is long known that many thiotrophic bacteria can create and survive very low pH values. A well-studied example is *Thiobacillus ferrooxidans* (now *Acidithiobacillus ferrooxidans*), which causes problems in acid mine drainage but can also be used for ore leaching. Only recently a number of alkaliphilic thiotrophic bacteria have been isolated (Sorokin and Kuenen, 2005).

Among the free-living thiotrophic bacteria, there is a morphological conspicuous group of large or even gigantic cells with inclusions of elemental sulfur. These large sulfur bacteria are widespread in nature, but are difficult to cultivate. *Beggiatoa* is the longest known, best studied, and probably also the most abundant genus among the morphologically conspicuous sulfur bacteria. They form multicellular, highly motile filaments of several millimeters to centimeter length which are 1–200 μm in diameter. Other genera of morphologically conspicuous sulfur bacteria are *Thioploca*, *Thiomargarita*, *Thiothrix*, *Achromatium*, and *Thiovulum* (Schulz and Jørgensen, 2001). Among the genera *Beggiatoa*, *Thioploca*, and *Thiomargarita*, there are giant forms with vacuoles used for the internal accumulation of nitrate,

which serve as an alternative electron acceptor for sulfide oxidation. With the exception of *Thiovulum* all morphologically conspicuous sulfur bacteria are within the gammaproteobacteria. *Thiovulum* is a member of the epsilonproteobacteria and is closely related to smaller free-living thiotrophic bacteria, which only recently have been recognized to be widespread sulfide oxidizers at hydrothermal vents (Campbell et al., 2006). Habitats with very high sulfide fluxes such as hydrothermal vents often favor the growth of a vibroid epsilonbacterium called *Candidatus Arcobacter sulfidicus*, which oxidizes sulfide rapidly to elemental sulfur. The resulting filaments of elemental sulfur are left behind (Wirsén et al., 2002).

Endosymbionts

Since the discovery of abundant life at hydrothermal vent systems in 1977 it took several years before it was recognized that the gutless tube worm *Riftia* found in high numbers at vents lives on energy conserved by endosymbiotic thiotrophic bacteria (Cavanaugh et al., 1981). The bacteria live on sulfide and oxygen provided by the host and use this energy source to reduce CO₂ to organic carbon compounds, which they share with their host. Many such tight associations between invertebrate animals and thiotrophic bacteria have been reported since the first discovery not only from vent systems but also from other sulfidic marine environments. Endosymbiosis with thiotrophic bacteria seems to be especially common among Mollusca (e.g., clams and mussels) and Annelida (e.g., tube worms) (Cavanaugh et al., 2006). None of the endosymbiotic bacteria could yet be grown outside of its host, but an abundance of information was obtained by using culture-independent methods. Most endosymbiotic thiotrophs are members of the gammaproteobacteria but a few symbionts belong to the epsilonproteobacteria. Usually host animals of one species are found to contain the same or closely related bacteria, indicating a close symbiotic association. For the clam *Calyplogena* there are indications that the symbiont is transferred directly from mother to offspring (Cary and Giovannoni, 1993), whereas the tube worm *Riftia* seems to acquire symbionts de novo from the environment (Laue and Nelson, 1997). For many host animals the mode of infection with the symbiont is not clarified yet (Cavanaugh et al., 2006).

Ectosymbionts

Virtually every larger organism is to some degree colonized by bacteria living on their surface. These so-called epibionts may have harmful, beneficial, or neutral effects on the host. In sulfidic environments thiotrophic bacteria frequently populate organisms such as ciliates, shrimps, or gastropods (Ott et al., 2004). In some cases, it could be shown that the host is feeding on these bacteria or may even provide conditions favoring the growth of thiotrophic bacteria. In other cases, the benefit for the host seems to lie in the detoxification of sulfide by the

epibionts or no obvious benefit could be observed (Ott et al., 2004).

Summary

Thiotrophic bacteria (or sulfur bacteria) live by the oxidation of sulfide with oxygen or nitrate as electron acceptor. This lithotrophic metabolism is widespread among bacteria and also found in some archaea. Among the gammaproteobacteria, a group of giant bacteria is specialized on oxidizing sulfide with nitrate, which is accumulated in a vacuole. Many thiotrophic bacteria live in symbiosis with higher organisms either as endo- or as ectosymbionts.

Wadden Sea: name of the world’s largest tidal flat system in Central Europe

Definition

Tidal Flat. A wide and almost flat coastal area between the mean upper and lower tidal seawater levels (eulitoral) exposed to the rhythmic tidal water movements. It consists of unconsolidated sediments and is bordered toward the land by permanently emerged areas and toward the sea by the permanently submerged sublitoral zone.

Introduction

Tidal flats occur worldwide in shallow coastal regions: in the tropics, subtropics, temperate zones, and subpolar, and polar regions. In the tropics and subtropics, such as at various regions of the east coast of South America, in Africa, Bangladesh, Indonesia, and Australia, tidal flats are closely associated with mangrove ecosystems. In other places, such as Mauretania, the Persian Gulf, and the coast of Texas, USA, tidal flats are either wide and open coastal stretches or protected by barrier islands. Large tidal flat

areas adjacent to marshlands exist on the Atlantic coast of the USA (North/South Carolina, Georgia) and Canada (Nova Scotia, Bay of Fundy), Korea, and in Europe along the Atlantic coast (Portugal, Spain, France, and Great Britain), and the North Sea. At the southern coast of the North Sea, the worldwide largest tidal flat system, the Wadden Sea ranges from The Netherlands (den Helder) through Germany to Denmark (Esbjerg). Subpolar and polar tidal flat systems are found in southern Chile, Alaska, and Siberia. Tidal flats may also develop in shallow estuaries, and thus their sediments may partially exhibit riverine properties.

A special type of tidal flats is wind-induced; these wind flats form along shallow coastlines with very little tidal water movements but occasionally persistently strong winds. The winds lead to the emergence or submergence of shallow areas for irregular periods, and the flats are characterized by microbial mats and sediments similar to those of regular tidal flats.

Formation and shaping forces

Along shallow coastlines with little wave action, the rhythmic incoming and outgoing tidal currents are the main driving forces for establishing and structuring tidal flats. A critical tidal range of at least 1 m is a prerequisite for the formation of a tidal flat. The incoming tide imports dissolved nutrients and particulate inorganic and organic matter, which settle out during reduced water movement at slack tide. This hydrographic energy gradient leads to a fractionation of the suspended material according to its settling properties. The finest material, the mud fraction (>50% of the material with a particle size <63 µm and the highest content of organic carbon up to 10% of dry weight) settles at the lowest current velocity and thus in the shallowest and least energetic zones. The other fractions consist of sandy (<5% mud) and mixed sediments (5–50% mud) and form the bulk of the sediment in highly and intermediate energetic areas (Chang et al., 2006). As a consequence, material and nutrients accumulate in tidal flats and provide the basis for highly productive ecosystems (Postma, 1981). Additional input of particulate organic and inorganic matter and nutrients may come from the adjacent coastal areas permanently emerged and/or by pore water (Kasten, this volume) and groundwater via tidal pumping (only inorganic nutrients and dissolved organic matter). Export of matter occurs mainly in the dissolved form and net export of particulates occurs only when re-suspension exceeds sedimentation for more than a tidal cycle, during storm events. The interplay of coastal and tidal currents, settling, re-suspension, and fractionation of suspended matter and sediment, results in the formation of typical depositional features, such as banks, islands, barrier island systems with distinct sediment structures, and drainage channels of different sizes and depths (Figure 1). Because of the ample nutrient supply, tidal flats are hot spots of marine productivity and biodiversity.

Definition

Tidal Flat. A wide and almost flat coastal area between the mean upper and lower tidal seawater levels (eulitoral) exposed to the rhythmic tidal water movements. It consists of unconsolidated sediments and is bordered toward the land by permanently emerged areas and toward the sea by the permanently submerged sublitoral zone.

Introduction

Tidal flats occur worldwide in shallow coastal regions: in the tropics, subtropics, temperate zones, and subpolar, and polar regions. In the tropics and subtropics, such as at various regions of the east coast of South America, in Africa, Bangladesh, Indonesia, and Australia, tidal flats are closely associated with mangrove ecosystems. In other places, such as Mauretania, the Persian Gulf, and the coast of Texas, USA, tidal flats are either wide and open coastal stretches or protected by barrier islands. Large tidal flat

areas adjacent to marshlands exist on the Atlantic coast of the USA (North/South Carolina, Georgia) and Canada (Nova Scotia, Bay of Fundy), Korea, and in Europe along the Atlantic coast (Portugal, Spain, France, and Great Britain), and the North Sea. At the southern coast of the North Sea, the worldwide largest tidal flat system, the Wadden Sea ranges from The Netherlands (den Helder) through Germany to Denmark (Esbjerg). Subpolar and polar tidal flat systems are found in southern Chile, Alaska, and Siberia. Tidal flats may also develop in shallow estuaries, and thus their sediments may partially exhibit riverine properties.

A special type of tidal flats is wind-induced; these wind flats form along shallow coastlines with very little tidal water movements but occasionally persistently strong winds. The winds lead to the emergence or submergence of shallow areas for irregular periods, and the flats are characterized by microbial mats and sediments similar to those of regular tidal flats.

Formation and shaping forces

Along shallow coastlines with little wave action, the rhythmic incoming and outgoing tidal currents are the main driving forces for establishing and structuring tidal flats. A critical tidal range of at least 1 m is a prerequisite for the formation of a tidal flat. The incoming tide imports dissolved nutrients and particulate inorganic and organic matter, which settle out during reduced water movement at slack tide. This hydrographic energy gradient leads to a fractionation of the suspended material according to its settling properties. The finest material, the mud fraction (>50% of the material with a particle size <63 µm and the highest content of organic carbon up to 10% of dry weight) settles at the lowest current velocity and thus in the shallowest and least energetic zones. The other fractions consist of sandy (<5% mud) and mixed sediments (5–50% mud) and form the bulk of the sediment in highly and intermediate energetic areas (Chang et al., 2006). As a consequence, material and nutrients accumulate in tidal flats and provide the basis for highly productive ecosystems (Postma, 1981). Additional input of particulate organic and inorganic matter and nutrients may come from the adjacent coastal areas permanently emerged and/or by pore water (Kasten, this volume) and groundwater via tidal pumping (only inorganic nutrients and dissolved organic matter). Export of matter occurs mainly in the dissolved form and net export of particulates occurs only when re-suspension exceeds sedimentation for more than a tidal cycle, during storm events. The interplay of coastal and tidal currents, settling, re-suspension, and fractionation of suspended matter and sediment, results in the formation of typical depositional features, such as banks, islands, barrier island systems with distinct sediment structures, and drainage channels of different sizes and depths (Figure 1). Because of the ample nutrient supply, tidal flats are hot spots of marine productivity and biodiversity.

Tidal Flats, Figure 1 A tidal flat with sand banks and tidal channels of the East Frisian Wadden Sea, Germany. (Photo: S. Kotzur.)

Recent studies have shown that settling of suspended material on tidal flats is not purely hydrodynamically and physico-chemically driven. Instead bacteria associated with the suspended material actively enhance the aggregation of suspended particles, followed by the sinking of the aggregated material at slack water (Chang et al., 2006; Lunau et al., 2006). During periods of low microbial activity, such as during winter in temperate regions, aggregation is low and suspended particles that persist in the water column are more abundant and smaller in size than during the warmer, growing season. The consolidation of sediment is enhanced by biofilms/microbial mats (Neu, Reitner, this volume) at the sediment-water interface and the associated production of exopolymetric substances (EPS, see Decho, entry *Extracellular Polymeric Substances (EPS)*, this volume), consisting mainly of polysaccharides and proteins, which glue together the fine primary sediment particles (Stal, 2003). As these biofilms are more biologically active during the enhanced temperatures of the spring and summer growing seasons, the sediments are more subject to re-suspension and erosion during periods of low temperature in fall and winter (Chang et al., 2006).

Under conditions when ice may cover large areas of tidal flats, such as during particularly cold winters in the temperate zone or during regular winters in subpolar and polar regions, tidal movement of ice flows can cause considerable erosion of the unconsolidated surface sediments.

Geobiology of tidal flats

The high productivity of tidal flats is reflected in their use as resting and overwintering areas for myriads of

migrating birds, which feed on the infauna such as molluscs, crustaceans, and worms. The food bases for these animals that rework and often bioturbate the tidal flats are autotrophic and heterotrophic microbes thriving in the water column, at the sediment-water interface and within the sediment (Reise, 2002). Primary producers in the water column are dominated by pennate diatoms (Bacillariales) in the temperate and polar zones, and diatoms, dinoflagellates, and coccolithophorids in subtropical and tropical regions. The suspended matter in the water column is heavily colonized by heterotrophic bacteria which decompose a substantial part of the available organic matter and also affect the aggregation and thus deposition of the settling material. In the oxic layer of the biofilms/microbial mats at the sediment-water interface, the dominant primary producers are filamentous cyanobacteria (Friedl, this volume), and diatoms (Stal, 2003). Because of the high primary production rates and the import of organic matter, mineralization rates of organic matter and thus oxygen consumption in the sediment is very high, resulting in anoxic conditions. Hence, anoxic microbial processes largely dominate within sediments, greatly affecting the formation and diagenesis of these sediments (Mackenzie, this volume).

The composition of the tidal flat-associated microbial communities is a function of the available light, pore water advection, and redox conditions, i.e., the availability of organic carbon, electron acceptors, and donors. The shapes of the redox profiles within the sediments, i.e., oxygen and sulfide concentration (Böttcher, this volume), are a function of sediment structure, grain size, pore water advection, and the metabolic activities of the microbes. Anoxygenic phototrophic bacteria contribute

Tidal Flats, Figure 2 Farbstreifensandwatt, layers from top to bottom – brown surface: Diatoms; red: Cyanobacteria associated with purple sulfur bacteria (*Chromatiaceae*); olive: Green sulfur bacteria (*Chlorobiaceae*); white/gray: Sulfidic precipitates. A black sulfidic zone of sulfate reduction is missing in this example because of lack of iron. Scale bar: 1 cm. (Photo: H. Cypionka, www.microbiological-garden.net.)

to CO₂-fixation by oxidizing sulfide. When the sediment remains undisturbed, a vertical zonation of the autotrophic communities may form distinctly colored layers, the so-called *Farbstreifensandwatt* (Stal et al., 1985; Figure 2), with a brownish-green layer at the top (diatoms), followed by a blue-green (cyanobacteria), a pink (purple sulfur bacteria), a green (purple non-sulfur bacteria), and a black layer at the bottom (sulfate reducers). Even though sulfate reduction (Cypionka, this volume) is commonly the most important process in forming the black, sulfide-dominated anoxic sediments in tidal flats, other anoxic processes contribute to the decomposition of organic matter: fermentation, denitrification, reduction of manganese and iron, and anaerobic methane oxidation (Boetius, this volume). These processes lead to the deposition of various reduced inorganic compounds and leftover of refractory organic matter, thus structuring the sediments on a long-term range and to a depth of several meters. Even though the general microbial processes in the oxic and anoxic sediments are well-characterized, the *Bacteria* and *Archaea* involved are far from being well-described. There is some information on the partitioning of some of the major

phylogenetic prokaryotic groups in near-surface sediments (Llobet-Brossa et al., 1998; Musat et al., 2006; Wilms et al., 2006). Some players in the major processes are available as isolated strains, but many more are identified only by genetic fingerprinting, i.e., sequencing of the 16S rRNA gene or of functional genes, and the microbes are not yet isolated. Some of the tidal flat microbes appear to be closely related to prokaryotes of the deep biosphere.

Mud flats versus sand flats

The composition of the inorganic sediment in the tidal flats may vary considerably but has little influence on the general grain size distribution. Depending on the geologic setting and the coastal environment, quartz, volcanic minerals, or biogenic carbonates can dominate or constitute varying proportions of the inorganic components of the sediments. Grain size and organic carbon content differ markedly in mud flats and sand flats. The smaller grain size and higher organic content of the mud flats result in a much more compact structure and a lower pore water volume and permeability. These characteristics have led to the traditional view that decomposition rates of organic carbon are much higher in mud flats than in sand flats. Recent studies, however, have shown that mineralization rates of organic carbon in sand flats are at least as high as and often higher than in mud flats (De Beer et al., 2005). In sand flats with a high pore water volume, oxygen supply is much higher than in mud flats, supporting high aerobic mineralization rates and leading to a lower content of organic carbon. Hence, the low content of organic carbon in sand flats appears not to be a result of the lower input of organic matter or reduced microbial activities as compared to mixed or mud flats but instead reflect more favorable conditions for the microbial decomposition of organic carbon.

Geologic age

Recent tidal flats are young geobiological systems on a geologic time scale and originated in the Holocene. They typically developed in the course of the sea water level rise in shallow and flat coastal regions during the last 10,000 years after the Pleistocene, when large amounts of sediments were deposited.

Related term

Sabkha: Almost flat, vegetation-free coastal areas above the mean and upper tidal seawater level in arid subtropical regions like at the Persian and Arabian Gulf. They are covered by salt deposits of the evaporating seawater and other crystalline deposits of halite, anhydrite, and gypsum, and by microbial mats of filamentous cyanobacteria.

Summary

Tidal flats are almost flat coastal areas between the mean upper and lower tidal sea water levels and a tidal range of at least 1 m and occur in all climatic regions. They are

structured by tidal channels and banks, and accumulate particulate matter which settles out at sites of reduced water movement. As a consequence, sediment layers are formed which rapidly become anoxic below the surface because of the intense microbial decomposition processes. Due to the high input of organic matter, tidal flats are one of the most productive ecosystems in the world; this productivity is fueled by microbial processes in the water column and within the sediments of the tidal flat regions.

ToF-SIMS

Peter Sjövall, Jukka Lausmaa
 SP Technical Research Institute of Sweden, Chemistry and Materials Technology, Borås, Sweden

Definition

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is a method for chemical microanalysis of solid surfaces (Benninghoven, 1994; Belu, 2003; Vickerman and Briggs, 2001). The method can be used to obtain detailed information of the organic and inorganic composition of samples at a spatial resolution down to <1 µm. It is a highly surface-sensitive method, providing chemical information about the uppermost molecular layers only. The analysis is based on mass spectrometry and requires no preselection or labeling of the substances to be analyzed.

In a ToF-SIMS measurement, the sample is bombarded by a pulsed, focused, high-energy ion beam (primary ions) that causes atoms, molecular fragments, and intact molecules to be ejected from the sample surface. A small fraction of the ejected particles will be ionized (secondary ions). The secondary ions are extracted and directed into a time-of-flight (ToF) mass analyzer, where they are separated with respect to mass to charge ratio. The resulting mass spectrum represents a chemical fingerprint from the sample surface at the point of impact of the primary ion beam (Figure 1).

Characterization of the chemical substances present on the sample surface is done by identification of the ions corresponding to the peaks in the mass spectrum, in a similar way as in other mass spectrometric techniques, such as GC/MS and LC/MS. The high mass resolution of the ToF analyzer (typically $m/\Delta m \sim 5,000\text{--}10,000$) allows for detailed identification of the secondary ions.

The spatial information, i.e., the lateral distribution of the different chemical components on the sample surface, is obtained by scanning the primary ion beam over the sample surface and recording separate mass spectra from a large number of points (pixels) within the analysis area. The acquired data can be presented in different ways: (a) as mass spectra of the total analysis area or selected regions of interest, (b) as ion images, in which the signal intensity distribution from ions representing specific elements or compounds are displayed as variations in brightness over the analysis area (see Figures 1 and 2), or (c) as time evolutions of specific ion signal intensities during ion etching using a separate ion beam (depth profiling).

An important advantage of the ToF-SIMS technique, in relation to other SIMS methods, is that the ToF mass analyzer allows for so-called static SIMS analysis, i.e., analysis of the undamaged surface before the mass spectrum has been significantly altered by the molecular damage caused by the primary ions. In dynamic SIMS, the sample surface is subjected to considerably higher primary ion dose

structured by tidal channels and banks, and accumulate particulate matter which settles out at sites of reduced water movement. As a consequence, sediment layers are formed which rapidly become anoxic below the surface because of the intense microbial decomposition processes. Due to the high input of organic matter, tidal flats are one of the most productive ecosystems in the world; this productivity is fueled by microbial processes in the water column and within the sediments of the tidal flat regions.

ToF-SIMS

Peter Sjövall, Jukka Lausmaa
 SP Technical Research Institute of Sweden, Chemistry and Materials Technology, Borås, Sweden

Definition

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is a method for chemical microanalysis of solid surfaces (Benninghoven, 1994; Belu, 2003; Vickerman and Briggs, 2001). The method can be used to obtain detailed information of the organic and inorganic composition of samples at a spatial resolution down to <1 µm. It is a highly surface-sensitive method, providing chemical information about the uppermost molecular layers only. The analysis is based on mass spectrometry and requires no preselection or labeling of the substances to be analyzed.

In a ToF-SIMS measurement, the sample is bombarded by a pulsed, focused, high-energy ion beam (primary ions) that causes atoms, molecular fragments, and intact molecules to be ejected from the sample surface. A small fraction of the ejected particles will be ionized (secondary ions). The secondary ions are extracted and directed into a time-of-flight (ToF) mass analyzer, where they are separated with respect to mass to charge ratio. The resulting mass spectrum represents a chemical fingerprint from the sample surface at the point of impact of the primary ion beam (Figure 1).

Characterization of the chemical substances present on the sample surface is done by identification of the ions corresponding to the peaks in the mass spectrum, in a similar way as in other mass spectrometric techniques, such as GC/MS and LC/MS. The high mass resolution of the ToF analyzer (typically $m/\Delta m \sim 5,000\text{--}10,000$) allows for detailed identification of the secondary ions.

The spatial information, i.e., the lateral distribution of the different chemical components on the sample surface, is obtained by scanning the primary ion beam over the sample surface and recording separate mass spectra from a large number of points (pixels) within the analysis area. The acquired data can be presented in different ways: (a) as mass spectra of the total analysis area or selected regions of interest, (b) as ion images, in which the signal intensity distribution from ions representing specific elements or compounds are displayed as variations in brightness over the analysis area (see Figures 1 and 2), or (c) as time evolutions of specific ion signal intensities during ion etching using a separate ion beam (depth profiling).

An important advantage of the ToF-SIMS technique, in relation to other SIMS methods, is that the ToF mass analyzer allows for so-called static SIMS analysis, i.e., analysis of the undamaged surface before the mass spectrum has been significantly altered by the molecular damage caused by the primary ions. In dynamic SIMS, the sample surface is subjected to considerably higher primary ion dose

ToF-SIMS, Figure 1 Schematic illustration of the ToF-SIMS analysis technique.

ToF-SIMS, Figure 2 Examples of ion images from ToF-SIMS analysis of a freeze-dried mouse brain tissue section. The images show the signal intensity distributions of secondary ions specific to four different lipids at three different magnification levels. The inserted squares indicate the analysis area at the next magnification level.

densities, which means that the analysis is done on a molecularly damaged and continuously eroding surface. As a consequence, ToF-SIMS is capable of providing detailed molecular information of, e.g., organic substances (up to around 5,000 Da), while dynamic SIMS is limited to

information on elements, isotopes, and small fragments on the surface.

For organic microanalysis using ToF-SIMS, the use of cluster ions, such as Bi_n^+ , $n = 3-7$, Au_3^+ , and C_{60}^+ , as primary ions has proven advantageous because

ToF-SIMS analysis of a microbial mat (microscopic cryosection)

ToF-SIMS, Figure 3 Ion images from ToF-SIMS analysis of a microbial mat cryosection retrieved from a methane seep in the Black Sea. The images show the signal intensity distributions of secondary ions of two different lipid biomarkers from methanotrophic archaea thriving in separate colonies within the microbial mat (ANME-1, tetraether lipids; ANME-2, hydroxyarchaeol, see chapters *Anaerobic Oxidation of Methane with Sulfate* and *Biomarkers (Organic, Compound-Specific Isotopes)*). Modified after Thiel et al. (2007a).

these ions produce high secondary ion yields for large (characteristic) organic ions in organic materials (Kollmer, 2004). In addition, it has been shown that some molecular information is retained in organic materials also after extensive bombardment by C_{60}^+ ions, making this ion suitable for ion etching (depth profiling) of organic materials (Wucher et al., 2007).

These capabilities make ToF-SIMS a promising tool for the investigation of organic biomarkers in different types of geobiological materials, particularly if only small sample amounts are available, or a high lateral resolution is desired. Examples are mineral phases in microbialites or microscopic samples (i.e., sections) of microbial mats (Figure 3; Thiel et al., 2007a, b; Sjövall et al., 2008). Furthermore, after hopanes and steranes have been successfully detected in different types of crude oils using ToF-SIMS (Sjövall et al., 2008; Siljeström

et al., 2009), the identification of authentic biomarkers in single oil inclusions of ancient rocks now appears to be within reach (Siljeström et al., 2010).

³University of California, Riverside, CA, USA

Synonyms

Ichnofossils; Neoproterozoic

Definition

Neoproterozoic trace fossils give us the earliest signs of animals moving on or just below the sea floor typically in the form of small horizontal unbranched trails and furrows. Despite their modest appearances, these trace fossils are important in that they provide an undisputable minimum age for the appearance of bilaterian animals. Remarkable are the recent discoveries of the Ediacaran organisms, *Kimberella* and *Dickinsonia*, in association with their trace fossils. These associations suggest exploitation of microbial mats, and a similar behavior probably explains also the simple horizontal Neoproterozoic trace fossils.

Introduction

Much of the Neoproterozoic sedimentary record is without the sign of burrows, trails, or other types of animal

trace fossils. A continuous record of widely accepted trace fossil appear only after about 560 Ma ago (Figure 1), and by comparison to the Phanerozoic the diversity and complexity is low and the size and depth of bioturbation are modest and generally considered in terms of a few millimeters. Indeed, though the transition between Ediacaran and Phanerozoic ichnofossil assemblages is somewhat gradual, the difference is nevertheless striking, notably in what is missing in the former. The Ediacaran lacks any evidence of trace fossils produced by animals with arthropod-type appendages, and traces showing adjustment to sedimentation (spreiten). There is little evidence for permanently maintained open burrows, and there are essentially no complex burrow systems. The Ediacaran trace fossil record is almost exclusively known from shallow-water marine deposits. Temporal trends in Ediacaran trace fossils are as yet tentative, but it can be noted that no trace fossils are currently known from the oldest associations of Ediacara-type fossils and that the first three-dimensional burrow systems, appearing shortly before the Ediacaran–Cambrian boundary, overlapping the range of some of the youngest Ediacara-type fossils (Figure 1). Among early studies, that of Seilacher (1956) was one of the first papers in which the contrasting nature of Proterozoic and Phanerozoic trace fossils was clearly stated, and the broad synthesis of Crimes (1987) provided a summary of the literature to date. The paper by Narbonne et al. (1987) outlined the Ediacaran–Cambrian sequence of trace fossils in sections in Newfoundland and set the stage for the subsequent definition of the base of the Cambrian on the basis of trace fossils in this region. Recent overviews and discussions of Ediacaran trace fossils, where the reader can find additional references to earlier papers, can be found in Jensen (2003), Droser et al. (2005), Seilacher et al. (2005), Jensen et al. (2006), Weber et al. (2007), Seilacher (2007), and Fedonkin and Vickers-Rich (2007). Currently, one of the major areas of study of Ediacaran trace fossils is, perhaps somewhat surprisingly, in deciding what is and what is not a trace fossil. In this brief overview, we will consider Ediacaran trace fossils under three headings.

Ediacaran trace fossils: true and false

Traditional trace fossils: Meaning trace fossils that can reasonably be assigned to ichnotaxa also described from the Phanerozoic. The most common Ediacaran trace fossils are essentially horizontal, unbranched, and with few exceptions small (a few millimeters wide), grooves or ridges on the upper or lower surface of sandstone beds (Figure 2c and d). These trace fossils, which are generally referred to as *Helminthoidichnites*, represent transitional movement through the sediment, close to the sediment–water interface, and there may be lateral raised ridges where sediment was pressed to the sides (e.g., Droser et al., 2005). They have been interpreted as mining of decaying microbial mats (Seilacher, 1999). Other possible Ediacaran trace fossils include

In this brief overview, we will consider Ediacaran trace fossils under three headings.

Ediacaran trace fossils: true and false

Traditional trace fossils: Meaning trace fossils that can reasonably be assigned to ichnotaxa also described from the Phanerozoic. The most common Ediacaran trace fossils are essentially horizontal, unbranched, and with few exceptions small (a few millimeters wide), grooves or ridges on the upper or lower surface of sandstone beds (Figure 2c and d). These trace fossils, which are generally referred to as *Helminthoidichnites*, represent transitional movement through the sediment, close to the sediment–water interface, and there may be lateral raised ridges where sediment was pressed to the sides (e.g., Droser et al., 2005). They have been interpreted as mining of decaying microbial mats (Seilacher, 1999). Other possible Ediacaran trace fossils include

Trace Fossils: Neoproterozoic, Figure 1 Schematic chart to show the approximate temporal distribution of trace fossils and selected other groups of fossils during the Ediacaran and early Cambrian. Only a selection of Cambrian trace fossil types is depicted. Note that trace fossils are only known from the latest part of the Neoproterozoic, and postdate the Gaskiers glaciation. The age of Doushantuo embryos, currently the oldest direct evidence for probable animals, is uncertain. Approximate position of glaciations is indicated by boxes with filled triangle. Abbreviations: A, Avalon association; N, Nama association; W, White Sea association.

small star-shaped forms and simple vertical tubes, but these are rare.

Ediacara-type organisms associated with their trace fossils: These remarkable fossils are known from northern Russia and South Australia. The possibly mollusc-grade *Kimberella* has been found associated with radial fan-shaped structures (Figure 2e and f) apparently representing raspings as well as possible traces of movement (Fedonkin et al., 2007). *Dickinsonia* has been found associated with disjunct rows of imprints (Figure 2g), perhaps representing pulses of degradation of a microbial mat (Gehling et al., 2005). These associations are all the more remarkable because associations of trace fossils with their producers are exceptionally rare in the Phanerozoic in normal marine settings.

False and doubtful Neoproterozoic trace fossils: The list of purported Ediacaran trace fossils is in fact quite extensive but many of these are now believed to be better explained as body fossils (Seilacher et al., 2005; Droser et al., 2005; Jensen et al., 2006). Common examples are *Yelovichnus* and *Palaeopasichnus*, which consist of short series of closely spaced kidney- or sausage-shaped objects (Figure 2a and b). Rather than trace fossils, these long-ranging forms, may have been algal or xenophyophore protists (Seilacher et al., 2005). Other supposed trace fossils represent the three-dimensional preservation of tubular organisms (Figure 2h) (Droser and Gehling, 2008). The evaluation of some of these purported Ediacaran trace fossil remains problematic. For example, *Nenoxites* might be an early example of a back-filled burrow (Seilacher et al., 2005). It is, however, clear that a considerable

non-trace fossil Ediacaran organismal diversity is hidden here.

Broader significance of Neoproterozoic trace fossils

Sediment properties and paleoecology: The rise of bioturbation had dramatic effects on sediment properties as well as on seafloor ecology, as entailed in the agronomic revolution or Cambrian substrate revolution (Seilacher, 1999; Bottjer et al., 2000). The gradual appearance of deeper and more intense bioturbation and by larger animals that took place during the late Ediacaran and early Paleozoic led to a shift from a seafloor largely covered with microbial mats and with a sharp sediment–water interface to a biogeochemically more active and deeper zone of surface sediments (McIlroy and Logan, 1999; Droser et al., 2002; Meysman et al., 2006). Many late Ediacaran and early Cambrian organisms may have had a lifestyle adapted to mat grounds (including the early trace fossil-makers) and a relatively firm muddy sea floor and these would have been negatively affected by the rise of bioturbation (Seilacher, 1999; Bottjer et al., 2000; Dornbos, 2006).

Evolution of metazoans: The Ediacaran trace fossil record is important in the discussion of the appearance of metazoans and in particular that of mobile animals. An obvious but important point is that the preservation potential of a trace fossil is decoupled from that of its producer. Thus, one line of argument goes that the appearance of trace fossils is unlikely to substantially postdate the appearance of mobile benthic animals and that the

Trace Fossils: Neoproterozoic, Figure 2 Ediacaran trace fossils (c–g) and trace fossil-like organisms (a, b, and h) (a) *Yelovichnus*, branching sets of collapsed, crescentic-tubes (b) *Palaeopascichnus*, a serial set of lozenge-shaped tubes with collapsed centers (c and d) *Heminthoidichnites*, groove trails with levees; junctions represent level changes by one trail (e and f) Casts of fan-shaped sets of bifid rasping traces in a microbial mat (g) Low-relief casts of two serial resting traces made by a single specimen of *Dickinsonia costata* (d) Composite casts of large, partly filled, tubular fossils. All from the Ediacara Member of South Australia. Scale bars correspond to 2 cm. Except for (c) and (d), all fossils are on bed soles.

radiation of bilaterian animals would have occurred in animals of a size that would readily leave a trace fossil record (Budd and Jensen, 2000; Jensen et al., 2005). The late Ediacaran appearance of trace fossils and the subsequent radiation at the Ediacaran–Cambrian boundary fits in with evidence from diverse fossil groups (and at least some molecular clock studies) of the appearance of increasingly diverse ecosystems following the Marinoan glaciation (Peterson and Butterfield, 2005; Butterfield, 2007) (Figure 1). Organisms other than metazoans are potential trace fossil makers (Matz et al., 2008) but the Ediacaran to Cambrian trace fossil diversification can only be explained as being part of a metazoan radiation. It is not known to what extent the types of trace fossils found in the Ediacaran was the result of limited neurological sophistication, limited capability to burrow deeply and/or withstand anoxic sediments or if the type of trace fossil largely reflect a particular type of feeding adapted to microbial mats in an environment with little competition. It has been suggested that the appearance of deeper burrows were a response to increased predation (e.g., Dzik, 2005).

Summary

Animal trace fossils first appear close to the end of the Neoproterozoic era typically in the form of simple horizontal burrows or trails, a few millimeters wide; although, the exact diversity of Ediacaran trace fossils is currently a hot topic. Particularly noteworthy is the occurrence of trace fossils made by the Ediacara-type organisms *Dickinsonia* and *Kimberella*. The appearance of Neoproterozoic trace fossils and their subsequent radiation at the Ediacaran–Cambrian transition most likely correspond to the diversification of animals and ecosystems at this time.

The rise of bioturbation probably played an important role in structuring early benthic ecosystems.

Travertines (in definition of Pentecost, 2005)

Definition

Tufas are calcareous deposits formed by inorganic or microbiologically induced precipitation of calcium carbonate in a wide range of freshwater environments, including streams, rivers, and lakes. Calcium carbonate precipitates principally on the tufa surface, and the term excludes lacustrine marl in which carbonate particles are formed in water column. Tufas are commonly developed in limestone areas from tropical to temperate climatic zones (Pentecost, 1995) showing a variety of geometry from a huge riverine barrage to a small mound developed just beside water springs (Pedley, 1990). Following the definitions of Ford and Pedley (1996) that tufas are carbonate deposited in cool or near ambient temperature freshwater and in open-air conditions, the term excludes carbonate deposits in hydrothermal water (travertines) and in a limestone cave (speleothems). Some workers prefer the definition of the term carrying textural implication because the term tufa was originally derived from a Greek word *tophos* which refers porous deposits, such as carbonate tufa and volcanic tuff.

Definition

Tufas are calcareous deposits formed by inorganic or microbiologically induced precipitation of calcium carbonate in a wide range of freshwater environments, including streams, rivers, and lakes. Calcium carbonate precipitates principally on the tufa surface, and the term excludes lacustrine marl in which carbonate particles are formed in water column. Tufas are commonly developed in limestone areas from tropical to temperate climatic zones (Pentecost, 1995) showing a variety of geometry from a huge riverine barrage to a small mound developed just beside water springs (Pedley, 1990). Following the definitions of Ford and Pedley (1996) that tufas are carbonate deposited in cool or near ambient temperature freshwater and in open-air conditions, the term excludes carbonate deposits in hydrothermal water (travertines) and in a limestone cave (speleothems). Some workers prefer the definition of the term carrying textural implication because the term tufa was originally derived from a Greek word *tophos* which refers porous deposits, such as carbonate tufa and volcanic tuff.

Processes

Water bearing the carbonate precipitation normally originates from an underground water system in carbonate rock where relatively high $p\text{CO}_2$ raises the concentration of dissolved calcium carbonate, but rarely from the mixture of hydrothermal water that contains a substantial amount of calcium and bicarbonate (Yoshimura et al., 2004). Tufa deposition requires supersaturation of water with respect to calcium carbonates, which are essentially achieved by CO_2 degassing from the water due to a large difference in $p\text{CO}_2$ between underground water and the atmosphere. The water actively degasses at sites where waterfalls or other obstructions along the passage cause water turbulence, and reaches high supersaturation (~ 10 times; Chen et al., 2004). Preferential deposition at the sites of high water turbulence often develops tufa mounds accompanied with water pools at the upcurrent side (Pedley, 1990). A tufa can grow at a much higher rate (typically several millimeter/year; Kano et al., 2003) than speleothems. However, continuous tufa growth has seldom lasted longer than 100 years because growth of the mounds changes watercourse in normal fluvial settings. Because of the circumstantial temperature and relatively low value of dissolved Mg/Ca, mineralogy of the most tufas is calcite.

Because tufas form outside in the light, unlike speleothems, phototrophic microbes (cyanobacteria, freshwater algae, and diatoms), and mosses normally live on the surface. The microbes form biofilms and influence carbonate precipitation rate and depositional textures of tufa. Especially, cyanobacteria are most common and have been considered to activate tufa deposition by photosynthetic uptake of CO_2 and bicarbonate that raises supersaturation of calcium carbonate (Mert, 1992), or by providing nucleation site of carbonate minerals (Pentecost and Riding, 1986). In such tufas, the calcite is deposited as fine-grained ($5\sim 10\ \mu\text{m}$ diameter) crystals encrusting a cyanobacteria sheath, which results in porous texture typically containing 50% of porosity (Kano and Fujii, 2000).

Annual lamination

Some tufas develop annual laminations consisting of both densely calcified and porous layers. Two different explanations have been proposed to account for the annual laminations. One is a seasonal change in the predominant microbial association seen in the biofilms covering the tufa surface (Freytet and Plet, 1996; Janssen et al., 1999; Arp et al., 2001). The tufa in the Franconian Alps, Germany, exhibits porous layers formed in winter–spring when diatom-dominated biofilm inhibits carbonate deposition on the tufa surface (Arp et al., 2001). However, the seasonal change in microbial association cannot always account for the lamination of some tufas, for instance, the ones from SW Japan dominated by cyanobacteria communities throughout the year (Kano et al., 2003). The annual laminations can be developed

due to seasonal changes in the inorganic calcite precipitation rate (Kano et al., 2003). Under a high rate during summer–autumn, the calcite crystals thickly encrust the cyanobacterial sheath until they become attached to neighboring encrusted sheathes and form a dense layer. In contrast, a low rate during winter–autumn results in the thinly encrusted sheathes and leaves abundant free space in a porous layer.

Climatic archive

Stable isotopes and trace elements of carbonate fraction of tufa deposits have been recently used for Holocene climatic studies (Zak et al., 2002; Makhnach et al., 2004; Garnett et al., 2004). Bulk $\delta^{18}\text{O}$ values primarily record latitude and altitude control on $\delta^{18}\text{O}$ of meteoric water (Andrews et al., 1997); although, evaporation largely affects the values in semiarid regions (Smith et al., 2004). On the other hand, $\delta^{13}\text{C}$ values are influenced by variable conditions including degassing of ^{12}C -enriched CO_2 (Pentecost, and Spiro, 1990), contribution of soil CO_2 (Hori et al., 2008), and vegetation (C3 vs. C4 plant; Kano et al., 2007), and therefore the interpretation is often problematic.

Because of their high depositional rate and development of annual lamination, tufas are potential archives of high-resolution paleoclimatic records (Andrews and Brasier, 2005; Andrews, 2006). Studies of modern specimens have reported cyclic changes in $\delta^{18}\text{O}$ and trace elements in tufa calcite that correspond to annually laminated textures, and therefore indicate seasonal change in water temperature (Matsuoka et al., 2001; Ihlenfeld et al., 2003). Tufa is also an excellent recorder of rainfall. A specimen from SW Japan exhibits a number of clay bands that were consistently correlated with heavy rainfall events of $>50\ \text{mm}$ (Kano et al., 2003). These approaches were recently applied to the Holocene tufa from Arizona (O'Brien et al., 2006).

Conclusion

Tufas are carbonate precipitates under the influence of photosynthetic microbes (cyanobacteria and algae), but the carbonate precipitation is primarily controlled by inorganic conditions, e.g., CO_2 degassing and raised supersaturation of the water. There are increasing evidences that stable isotopes and elemental geochemistry of the calcite fraction record clear environmental and climatic information.

Tufas provide high-resolution, but discontinuous paleoclimatic records from core and outcrop specimens, which can be dated by appropriate methods, such as U-Th dating of pure carbonate fraction, and radiocarbon composition of exceptionally preserved plant fragments. A promising approach in future research is combined investigation of speleothems and tufas from the same area. High-resolution temperature and rainfall records derived from tufas can add significant information to terrestrial paleoclimatology.

Definition

Reduction spheroids are small-scale (diameter: few millimeters to maximum about 20 cm) spheroidal bleached features in red-bed sediments characterized by the absence of hematite and often containing a mineralized core (center, [Figure 1](#)). Reduction spheroids result from local chemical reduction of ferric iron and other elements. Host rocks are marine and continental red beds and, more rarely, altered, hematite-stained crystalline rocks. Reduction spheroids have been described from many occurrences in red beds of widely variable age worldwide: Proterozoic of Canada (Tanton, [1948](#)); Cambro-Silurian marine red beds of the NE USA (Beutner and Charles, [1985](#)); Devonian continental red beds of Scotland (Parnell, [1985](#)); Carboniferous continental red beds of New Brunswick and Nova Scotia, Canada (Dyck and McCorkell, [1983](#)); Permian continental red beds of Germany (Eichhoff and Reineck, [1952](#); Mempel, [1960](#); Schreiter, [1930](#)), Switzerland (Hofmann, [1990](#), [1991](#)), Southwest England (Harrison, [1970](#); Perutz, [1940](#)), and Cretaceous radiolarian cherts of Oman (Hofmann, [1991](#)). Reduction spheroids characteristically consist of a spheroidal volume of rock from which hematite pigment has been dissolved. Central dark cores often display pronounced concentric zonation. The cores are strongly enriched in numerous redox-sensitive elements (dominant V, but also U, Se, As, Ni, Co, Cu, Ag, Au, PGE, and others). The dominant mineral in reduction spheroid cores is the vanadium mica roscoelite $KV_2AlSi_3O_{10}(OH)_2$. Uraninite is another very common mineral, leading to an often increased radioactivity of reduction spheroids ([Figure 2](#)). Arsenides of Ni, Co, and Cu are also quite common. Radiometric dating of roscoelite, uraninite, and

Reduction Spheroids, Figure 1 Reduction spheroids in Triassic red bed (marly dolomite), Chinle Formation, Paradox Valley, Colorado, USA. These reduction spheroids are strongly enriched in V, Cr, and Au. Diameter of larger reduction spheroid is 8 cm.

Pb-depleted haloes indicates late diagenetic ages (Hofmann, [1990](#); Hofmann and Frei, [1996](#)). Reduction spheroids often occur in large numbers in red beds and can constitute up to several vol% of the rock. Based on textural evidence, such as fracture-bound occurrences and mass-balance calculations (Hofmann, [1991](#)), reduction spheroids cannot be due to detrital organic-rich particles. Instead, the formation must be due to locally catalyzed redox reactions between a mobile reductant and oxidants. The presence of isotopically light sulfides in some cores (Hofmann, [1991](#)), indicating diagenetic sulfate reduction, as well as the need for a local catalyst, strongly favors a microbiological origin of reduction spheroids. Reductants may be mobile hydrocarbons or molecular hydrogen resulting from the radiolysis of pore water (Hofmann, [1992](#)). The formation of reduction spots is most likely due to chemolithotrophic communities. Kerogen-like organic matter is occasionally present at some localities (Curiale et al., [1983](#); Parnell, [1985](#)) but is lacking at many other occurrences (Hofmann, [1993](#)).

Conclusion

Reduction spheroids are very common in red-bed sediments, and there are strong indications for an origin due to redox reactions between a mobile reductant and oxidized elements locally catalyzed by microbial activity. Reduction spheroids are thus easily visible features resulting from redox processes catalyzed by a deep biosphere of sediments, and represent a type of biosignature that may also be present in oxidized rocks on Mars. Reduction spheroids contain small-scale

Reduction Spheroids, Figure 2 α -Autoradiographs of uranium-enriched reduction spheroid cores, Weiherfeld well, Permian of northern Switzerland. The accumulation of uranium reflects the heterogeneous distribution of reduction activity, consistent with microbial activity. Diameter of radioactive uranium-rich zone is (a) 5 mm and (b) 10 mm.

element enrichments that are in many ways analogous in element inventory, geochemistry, and mineralogy to ore deposits such as unconformity-related and roll-type uranium ores.

REEFS

Reefs are laterally confined submarine carbonate structures developed by the growth or activity of sessile benthic aquatic organisms, such as corals, bryozoans, sponges, algae, and microbes (Flügel and Kiessling, 2002). See entry “[Carbonate Environments](#)” for further reading and classification.

Synonyms

Waulsortian banks; Waulsortian buildups; Waulsortian mounds; Waulsortian mudbanks; Waulsortian reefs

Definition

Waulsortian mud mounds are characterized by different types of complex and highly structured fabrics of carbonate muds, texturally and genetically varied (both automicrites and allomicrites occur), with a variable content in skeletal components (heterozoan assemblages). Their origin is controversial although most authors advocate a microbial origin (calcite precipitation microbially induced). They were developed throughout the northern hemisphere in many parts of the World (Europe and North America) during the Carboniferous times (Lower Mississippian, mainly in the Tournaisian). These mud mounds grew on wider ramps and within basins in tropical “calcite seas,” immersed in a period of intense global changes (tectonic activity related with the Variscan orogeny and major sea-level changes).

Introduction

The term, from the Waulsort area, was first introduced by Dupont (1863) who studied and divided the Carboniferous Limestone of Belgium in six stratigraphic units. In the 1960s and 1970s, most of the carbonate buildups of Mississippian age were collectively named as “Waulsortian,” however, not all of them can be considered as true or classic “Waulsortian” as well as the whole Mississippian

bioconstruction spectrum can not be classified or assigned to the Waulsortian mud mounds (Figure 1). Some authors believe that the application of denominations like “Waulsortian,” “Waulsortian-like,” and “non-Waulsortian” buildups is of limited value because they do not mean a fast and clear idea about the geometry, composition, and/or the possible buildup origin. In fact, the use and meanings of the term “Waulsortian” have been controversial from their origin in the 19th century and has been not always used with clarity (see historical review by Lees, 1988).

The study of the Waulsortian mud mounds have been focused in several aspects, developed not always with the same profusion: (a) facies relationships and geometries (external morphology and internal structure); (b) allochems; (c) carbonate mud types; and (d) open space structures.

Facies and geometry

Waulsortian mud mound (Mud mound is considered here as just a descriptive, nongenetic, non-morphological term, to describe a type of bioconstruction dominated by carbonate mud (>50% of the rock volume)) facies are separated normally in Waulsortian massive facies, off-mound or coeval bottom facies and flank facies, which can or not occur.

Waulsortian limestones facies are massive, although bedding intervals can occur, and characteristically pale violet-grey to dark grey in color. In the field, the major lithological variations are based on changes of the following features: (1) carbonate mud content (dominance of “muddy” fabrics); (2) presence of coarsely calcite mosaics (dominance of “sparry” fabrics); (3) in situ fenestellid bryozoan fronds; (4) skeletal debris lenses, commonly crinoids and bryozoans; and (5) other entire fossils. These characters can occur combined in different proportions,

Waulsortian Mud Mounds, Figure 1 Mississippian bioconstruction spectrum, including mud mounds: (a) Buildups type's distribution based mainly on skeletal assemblages, summarized and simplified from Bridges et al. (1995); (b) Buildups type's distribution based mainly on main type of framework, modified from Aretz and Webb (2006). *EI* Ireland; *GB* Great Britain; *B* Belgium; *F* France.

resulting in fast laterally and vertically subfacies changes in few centimeters between: (1) bryozoan cementstones (fenestellid fronds, Figure 2a); (2) bryozoan wackestones (fenestellid fronds); (3) skeletal wackestones; (4) skeletal wackestones with "sparry fabrics" (Figure 2b); and (5) crinoidal-rich packstones.

Geometrically, they were formed by the aggregation of successive, laterally extensive banks, which developed final tabular-, knoll-, or sheet-growth morphologies (Figure 3). Growth morphologies are function of many variables, some of them related with: (1) the autochthonous carbonate mud production rate; (2) the ability of the autochthonous carbonate mud to construct depositional slopes (some of them up to 50 degrees); (3) the coeval sedimentation versus carbonate mud production relationship; (4) the sea floor topography; (5) the available accommodation space, etc.

Final dimensions vary from few meters, in the simple Waulsortian mud mounds, up to hundreds of meters in thickness and thousands of square kilometers across in some Waulsortian complexes or aggregates (Figure 3). In Ireland, the biggest Waulsortian complex crops range around 1 km in thickness and spread over 30,000 km².

Allochems

The allochems record in the Waulsortian mud mounds, in terms of volumetric importance, is fundamentally formed

by crinoids, bryozoans (mainly fenestrate), ostracods, brachiopods, and molluscs (gastropods, goniatites, lamelli-branches, and nautiloids). Sponge spicules (hyalosteliid) are common. Minority components such as foraminifers, calcified filaments of cyanobacteria, moravamminids, aoujgaliids also occur (some of them are considered as problematica taxa by some authors). Accessory allochems are trilobites, echinoid spines, serpulids, and clorophytes. Colonial rugose corals are very rare and they occurred exceptionally in the upper part of some of these mud mounds. Others as solitary forms and heterocorals are also uncommon. Non-skeletal grains as intraclasts can appear and be locally common in some parts and small, micritized radial oolites are very unusual.

Component assemblages models

First detailed systematic petrographic analyses of Waulsortian mud mounds were carried in Belgium by Lees et al. (1985) and 25 parameters were ranked according their volumetric importance. Four depth-related phases were distinguished using correspondence analysis. Later, following the same methodology, more than 30 mud mounds from Europe and North America were analyzed and they showed also the Belgium component assemblages (results summarized in Lees and Miller, 1995). Thus, four Waulsortian Phases (A–D) were established, and they have been interpreted as the mud mound growth

Waulsortian Mud Mounds, Figure 2 Classic Waulsortian facies: (a) bryozoan cementstones (scale bar = 5 cm) and (b) skeletal wackestone with stromatolite cavities. Ballybunnion outcrops, W Ireland.

from deep, subtidal, aphotic marine environments through to the photic zone (Figure 4):

- Phase A: fenestellids + crinoids + ostracods
- Phase B: resembles A + hyalosteliid sponge spicules
- Phase C: resembles B + plurilocular foraminifera
- Phase D: resembles C + cryptalgal coating, micritization (cement, cavity walls, grains), and calcareous algae.

In general, there is not a close correlation between the different component-assemblage phases and a determined aspect or facies at outcrop scale. Phase A represents the “classic” idea of Waulsortian facies, characterized by the fenestellid sheets with radial fibrous cements nucleated around the fronds (fenestellid cementstones) and pockets and lenses with crinoid debris. The content in fenestellid sheets tends to decrease in abundance in the rest of phases; in fact they are rare in Phase C. Sometimes they occur again in high proportions in Phase D, but bryozoans commonly were micritized before the cement nucleation.

The relationship between the mud mound biota and the off mound facies was systematically analyzed in New Mexico, where the exceptional quality of the outcrops (Figure 5a) allows this type of comparisons. Ahr and

Waulsortian Mud Mounds, Figure 3 Observed growth morphologies and facies relationships in Waulsortian mud mounds, redrawn and simplified from Lees and Miller (1995). a = Waulsortian facies; b = flank facies; c = off mound facies.

Stanton (1996), analyzed the frequency occurrence of 26 parameters on thin sections from different mounds, included Muleshoe mound (Alamogordo, Nunn, and Tierra Blanca phases from the lower to the upper part) and the off mound facies (Figure 5a and b).

Crinoids, fenestellid hash, and ostracods are the most abundant and similarly distributed fossils in both facies. In fact, in the off mound facies, most frequent fossils are crinoids, ostracods, fenestellid hash, sponge spicules, and echinoid spines (>80% of the thin sections) followed by mollusc and brachiopods shells, fragments of trilobites, and hyalosteliid spicules (Figure 5b). However, the abundance of skeletal components was low in both settings, although they were volumetrically more important and diverse on the mud mounds. Most of the variations could be related with taphonomic bias and differences in available habitats (cryptic spaces, soft, firm, and hard substrates) more suitable in/on mud mounds.

The systematic analysis of the biotic content from the off mound record was developed by Jeffery and Stanton (1996), and four component assemblages were established from deep to more shallow conditions:

- Assemblage I: crinoid/echinoderm debris, fenestellid hash, and ostracods

Waulsortian Mud Mounds, Figure 4 Qualitative distribution of components through the Waulsortian Phases (A, B, C, and D). Redrawn and modified from Lees and Miller (1995).

- Assemblage II: I + stacheiins (possible algae), rare salebrids (possible bryozoan), and commonly abundant sponge spicules
- Assemblage III: II + plurilocular foraminifera
- Assemblage IV: III + green algae

Biologically controlled contribution

The dominant macrobiota in the Waulsortian mud mound was formed by heterozoan assemblages, which never constituted a skeletal framework. Photosynthetic groups such as calcareous algae were very rare and uncommon to colonize these mud mounds. Crinoids and bryozoans have played an important role when they colonized and stabilized the slopes and mound surfaces. As skeletal producers, they formed favorable substrates (encrusters, cement nucleation, etc.) and they had also relative importance as allomicrite bafflers. Thus, the endemic macrofauna was composed by crinoids, fenestrate bryozoans, and sponges (Figure 6). The metabolism and decay of siliceous sponges could also favored the bacterial activity producing organomicrites, which would be added to the main autochthonous carbonate production in these mud mounds (biologically induced mechanism are argued by most authors). Opportunistic epi- and infauna biota could colonize the locally soft mound substrates and after their death contribute to the biodegradation with the skeletal debris (Figure 6).

Carbonate muds

The most important component in the Waulsortian mud mounds is the carbonate mud, paradoxically during many

decades its nature has been not considered or specifically studied. In fact, the origin of the carbonate muds and its ability to maintain steep slopes has been subject of much debate during years. Some authors have advocated for an external source followed by some kind of posterior accumulation mechanisms (hydrodynamic, baffling by bryozoans and crinoids, trapping and binding by bryozoans or other organisms). From the 1980s most part of the authors suggest a probable microbial origin for the carbonate mud, and a dominant in situ carbonate mud production is assumed.

The carbonate muds appear forming mudstone to packstone, although most works coincide in wackestone as the commonest texture. They are highly organized displaying successive generations of carbonate muds in geopetal relationship. They have been separated in primary muds (M1) and later muds (M2, M3, M4, etc.), all forming together the known polymuds (name coined by Lees and Miller, 1985, after the “multicomponent mudstones” concept of Lees (1964)). The earliest mud generation (M1) can represent less than 50% of carbonate mud volume. Lees and Miller (1995) subdivided the primary muds into three different subtypes (Figure 6):

- (M1a) optically dense micrites, often with filaments
- (M1b) paler biomicrites
- (M1c) peloidal micrites

A biofilm model has been proposed for the in situ primary mud production (Figure 6). The biofilm formed by bacterial cells, cyanobacterial filaments, and bacterial extracellular polymeric substances (EPS), induced the precipitation of high-magnesium calcite micrites (dense

Waulsortian Mud Mounds, Figure 6 Biofilm model with the process-response mechanisms proposed to Waulsortian mud mounds. (Simplified and modified after Lees and Miller, 1995.)

and peloidal ones). Biomicrites were formed by both reworking of dense or/and peloidal micrites and the skeletal debris input (Figure 6). Additionally, the biofilm could be used by other mud mound colonizers as a source of organic carbon. Carbonate mud production was not only reduced to the active biofilm mound surface, but also continued below the surface favored by the biofilm degradation during early burial (Figure 6). Dewatering, shrinkage, carbonate dissolution, and reworking processes produced the collapse of carbonate mud matrix. The collapse and successive reorganizations of the carbonate muds through the cavity system resulted in the final polymud fabrics. Later fractures and fissures could also have favored sediment inputs through the mound void system (Figure 6).

There are no available data on the quantitative distribution/contribution of the different primary muds through the Waulsortian phases. Filaments, characteristic in dense micrites (M1a) do not occur in phase A, whereas they are abundant in the rest of phases. As well as, cavities from phase D contain important volumes of geopetal peloids intercalated with early calcite cements. Thus an early, deep, nonfilamentous, non-photosynthetic cyanobacterial community has been suggested for the carbonate mud production in the Waulsortian phase A (Miller, 1986). In the same way, several microbial communities may have controlled the distribution/production of the different primary non-reworked mud textures (dense or peloidal micrites).

The distribution and typologies of carbonate mud, from the transitional facies to Waulsortian mud mound nucleation, were analyzed by Devusyst and Lees (2001), in western Ireland. *Precursor muds* are differentiated in function by their grumous or non-grumous character, bioclastic content, and contact relationship. They were grouped into two major types with six subtypes:

- Grumous types on basis of their apparent optical density, with three intergrading subtypes (codified as 1, 2 and 3). Types 1 and 2 are normally poor in skeletal debris; however, the dark optically dense type 3 contains abundant sponge spicules. All of them have been interpreted as automicrites. The grumous types are equivalent to the peloidal micrites (M1c) of Lees and Miller (1985, 1995).
- Non-grumous types: (1) gradational (into grumous muds) bioclastic wackestones; (2) distinct bioclastic wackestones; and (3) packstone matrix. The first subtype is also interpreted as automicrite whereas the others are seen as loose sediment.

The different precursor muds and other features were analyzed by correspondence analysis and a compositional gradient or trend was detected (Figure 7). The precursor muds display different textural and genetic types and culminate in the Waulsortian *polymuds* that contain both grumous and non-grumous muds (mainly non-grumous).

Waulsortian Mud Mounds, Figure 7 Observed relay pattern resulting from correspondence analysis of the precursor muds, polymuds, and associated features. Simplified and modified from Devusyst and Lees (2001). Vertical scales of boxes ranges from 0 up to 1, thus grey areas represent the frequency of presence. CFC = crypto-fibrous calcite; w = wackestone.

Open space structures

Waulsortian mud mounds were originally interpreted as reefs by Dupont (1881) who coined the term *Stromatactis* in 1881 to describe and interpret the “sparry masses” from Devonian mud mounds as recrystallized fossils. The stromatactis are a special type of cavities whose origin is still controversial. They have a characteristic shape, with a flat to undulose floor and irregular digitate roof and are filled by centripetal calcite cement, although internal sediment can also occur. Other terms like stromatactoid or stromatactis-like cavity are commonly found in the literature to describe similar features. They are common through the Precambrian up to the Jurassic mud mounds, (Bosence and Bridges, 1995) although can also appear in other types of limestones not just in muddy ones. A different hypothesis has been proposed to explain the stromatactis, which can be grouped in organic or inorganic models (see reviews by Bathurst, 1982; Flajs and Hüssner, 1993; Monty, 1995; Flügel, 2004, p. 194).

In Belgium, some mud mounds facies contain those described as undulating or tortuous “vein bleues” which were used, for many years, as a traditional criterion to characterize the Waulsortian facies and but was later abandoned (Lees, 1988).

Sheet-form cavities, similar as known zebra cavities, just few centimeters thick but several meters in length, are also typical in Waulsortian mud mounds. Their roofs

are not clearly associated with skeletal support and they have been interpreted as the result of dewatering and shear stress processes in the firm, gel-like consistence muds.

Stromatactis, the sheet-form and irregular shelter cavities have been considered early-formed cavity systems (Lees and Miller, 1995). Dissolution as well as physical processes like fracturing and internal erosion produce secondary cavities included fissures (Figure 6).

The size of the cavities tends to decrease through B and C phases and gets much complex in the D than in the others. Thus, "sparry" fabrics are common in phase A, whereas in B and C they tend to be muddier.

The shape and heterogeneity of the cavities seem to mainly be related with the skeletal content as well as the different carbonate mud textures and their distribution. Fillings as polymuds, cements (marine fibrous calcites are common), and their diagenetic sequences are also diverse (Meyers, 1974; Miller, 1986).

Conclusions

The understanding of the Waulsortian reefs, carbonate mudbanks, mounds, buildups, or mud mounds has evolved from the last two centuries.

The application of Waulsortian term is generally related to a group of diagnosis criteria: complex carbonate mud fabrics (polymuds), stratigraphic position (Middle-Upper Tournaisian-Lower Viséan), facies, component assemblages (Waulsortian phases), and the associated macrofaunas.

The Mississippian seas were colonized by a wide bioconstruction spectrum and not by Waulsortian mud mounds alone. Bacteria and cyanobacteria are suggested as primary producers in Waulsortian microbial mud mounds. The hypothesis about the distribution of Waulsortian mud mounds has been related with upwelling areas and methane seeps. Carbon sources and convincing models to explain such large volumes of radial fibrous calcite cements and continuous regional production of polymuds are still unrevealing.

Most part of the studies has been focussed on the allochems distribution that has been considered in detail by many authors. Few works are specifically dedicated to the analysis of the carbonated mud, main component in the Waulsortian mud mounds. However, more work would be necessary to analyze, quantify, and decipher the relationship between the allomicrite input and the automicrite production in mud mounds, particularly in Waulsortian ones, where clear microbialite frameworks are not always evident.

Summary

Waulsortian mud mounds are probably the most famous carboniferous bioconstructions. They were described first from Belgium outcrops, in the locality of Waulsort, two centuries ago. Later, they have been recognized and analyzed from several areas of Europe and North America.

The growth of these bioconstructions was controlled by the dominant autochthonous production of carbonate mud which has been explained by the activity of marine microbial benthic communities. The associated biota which colonized mud mound substrates was composed by heterozoan assemblages dominated by fenestrate bryozoans and crinoids. Detailed studies of these component assemblages have been a key to reconstruct regional gradients from deep subtidal, aphotic marine environments through the photic zone.

Today, there are no equivalent analogs to compare with such a spectacular mud mound development during the Tournaisian-lowermost Viséan period. Thus, they represent an excellent record to reconstruct and understand the paleoenvironmental and paleoecological relationships between microbial and nonmicrobial benthic communities through deep ramp to basin settings along the northern hemisphere during Lower Mississippian times.

WHALE AND WOOD FALLS

Steffen Kiel
 University of Göttingen, Göttingen, Germany

Synonyms

Biogenic substrates; Food falls; Nekton falls; Organic falls; Sunken wood

Definition

Whale fall: Carcass of a large marine mammal of the order Cetacea (whales) that has sunken to the seafloor.

Wood fall: A piece of wood that has sunken to the seafloor.

History

The first examples of specialized invertebrates inhabiting bones and wood in the *deep sea* (qv) were recognized during the deep-sea expeditions in the early to mid 1900s. Because these samples were recovered by dredging, the complexity of whale- and wood-fall ecosystems was not recognized before the advent of deep-sea research vessels. Pioneering experimental work on wood-falls was carried out in the early 1970s by Ruth Turner (1914–2000), using the deep-sea research vessel *Alvin*. This research came to a halt in the late 1970s when deep-sea *hydrothermal vent systems* (qv) and their fascinating fauna were discovered and *Alvin* was occupied by exploring these systems. The first deep-sea whale-fall ecosystem was accidentally discovered by Craig Smith during an *Alvin* dive in 1987 and consisted of a whale skeleton associated with many chemosymbiotic taxa that were also known from hydrothermal vents (Smith et al., 1989). Nowadays, whale-fall ecosystems are mainly investigated by sinking stranded whales which are then studied by submersibles and/or ROVs. The last major discovery in this field was *Osedax*, a “bone-eating” siboglinid worm living in symbiosis with bacteria that degrade bone lipids and cartilage (Rouse et al., 2004).

Bivalve-bored wood has been known from the fossil record for centuries, but reports on other invertebrate groups that utilized wood falls in the geologic past are rare, and entire fossil wood-fall ecosystems have only been described very recently (Kiel and Goedert, 2006b; Kiel et al., 2009). Fossil examples of deep-sea whale-fall ecosystems were discovered soon after the discovery of the modern ones and are especially common in uplifted deep-water sediments around the North Pacific margin (Squires et al., 1991; Kiel and Goedert, 2006a). Similar ecosystems were recently found on two late Cretaceous plesiosaur (a marine reptile) skeletons in Japan (Kaim et al., 2008).

Whale falls

Whale falls are the basis for the most species-rich deep-sea ecosystem, with more than 400 species known to date (Baco and Smith, 2003). Whale falls pass through three ecologic stages that vary in length and can overlap. At first the flesh of the whale carcass is removed by sleeper sharks, hagfish, and other scavenging deep-sea fishes. In the second stage small annelids and crustaceans consume the remaining particulate organic matter. The main source of nutrients during the third stage is the hydrogen sulfide (H₂S) generated by the anaerobic decay of bone lipids, which is utilized by species harboring chemotrophic endosymbionts or by species that graze on sulfur-oxidizing

Physicochemical characteristics

Zinc (Zn) is the 23rd most abundant element in the Earth's crust, and exists as a blue-whitish metal relatively weak with a melting point of 419.5°C and a boiling point of 907°C, with a density of 7.133 g/cm³ (Henkin, 1984). Zn consists of a mixture of the five stable isotopes ⁶⁴Zn (48.6%, atomic mass 63.9), ⁶⁶Zn (27.9%, atomic mass 65.9), ⁶⁷Zn (4.1%, atomic mass 66.9), ⁶⁸Zn (18.8%, atomic mass 67.9), and ⁷⁰Zn (0.6%, atomic mass 69.9) (Coplen et al., 2002). Moreover, six synthetic radioactive isotopes are known: ⁶²Zn, ⁶³Zn, ⁶⁵Zn, ⁶⁹Zn, ⁷²Zn, and ⁷³Zn. The atomic number is 30. Zinc metal is highly reactive and produces various different salts, but it is only stable in water as the Zn²⁺ ion and associated complexes and minerals. Its sulfates and chlorides are water-soluble and its sulfides, oxides, carbonates, phosphates, silicates, as well as organic complexes are water-insoluble (Henkin, 1984). Zinc, like many other metals, also exists as dissolved metal-sulfide cluster complexes (particularly Zn₃S₃ and Zn₄S₆⁴⁻), which can exist even in oxic river waters for extended periods and account for up to 20% of the total dissolved Zn in solution (Rozan et al., 2000). Zinc as an element is not available as a metabolic component as it only exists in the Zn²⁺ state in water, but the strong bonds formed with dissolved sulfide ions result in

highly insoluble ZnS mineral formation, which is strongly linked to sulfur-based microbial activity.

Abundance and distribution in the environment

Zinc is one of the world's principle ores and stands fourth among all metals in world production (behind iron, aluminum, and copper), used in a variety of ways from metal products to rubber production to medicines (USGS, 2008). The world's total reserve of this widely distributed metal is approximately 460 million tons in the year 2006 (Cohen, 2007). More than 80 zinc minerals are known; ZnS (as cubic sphalerite and hexagonal wurtzite polymorphs) and its weathering products are the most important minerals for commercial use (Henkin, 1984), with smithsonite (ZnCO₃) and willemite (Zn₂SiO₄) being important non-sulfide forms.

Zn ore deposition

The genesis of many types of ZnS ore deposits are often attributed to purely physicochemical processes, and the distinction between abiotic and potentially biotic process is often made based on the temperature of sulfide formation and subsequent ZnS mineral formation. At low temperatures (below 150–175°C), thermochemical sulfate reduction (TSR) is very slow (Goldhaber and Orr, 1995; Ohmoto and Goldhaber, 1997; Thom and Anderson, 2008), whereas the upper temperature limit for microbial sulfate reduction overlaps with the formation of many low-temperature deposits (Ledín and Pedersen, 1996; Druschel et al., 2002). ZnS ore depositional processes without microbial influence were, for example, probably due to depositional environments outside the range of temperatures where microorganisms can survive, and TSR is sufficiently fast for significant ore formation, such as observed for the formation of high temperature hydrothermal Pb–Zn ore deposits as, e.g., described for the Rhodopian metallogenic region

(Tarkian and Breskovska, 1989; Kaiser-Rohrmeier et al., 2004). On the other hand, Mississippi Valley-Type (MVT) deposits also form from highly saline brines, between 50°C and 200°C, and span depositional environments where abiotic and biotic factors may be responsible for zinc sulfide mineralization (Bastin, 1926; Druschel et al., 2002; Thom and Anderson, 2008). Siebenthal (1915) suggested, as early as 1915, that microbial sulfate reduction contributed to the formation of low-temperature strata-bound zinc sulfide deposits. However, there is considerable controversy associated with the interpretation of the complex paragenetic sequences responsible for Zn ore deposit formation, and it is entirely possible that some deposits experience both biological and abiotic ZnS formation at different times and in different places. Trudinger et al. (1972) reviewed the feasibility of biogenic ore formation and addressed three issues: (1) the environmental limits of biogenic sulfate reduction; (2) whether the age of biological sulfate reduction was coextensive with the ages of ancient deposits; and (3) whether the rates of sulfate reduction are sufficient for ore formation. Trudinger et al. (1972) concluded that the information at the time was not adequate to address these questions. However, in the last 30 years significant progress has been made on each of these issues to better evaluate the role of microorganisms in ore deposit formation (Druschel et al., 2002; Spangenberg and Herlec, 2006). Organic geochemical and isotopic indicators of biological sulfate reduction have been recently reported from some Pb and Zn deposits (Hu et al., 1998; Bechtel et al., 1998, 1999; Spangenberg and Herlec, 2006). Moreover, modern in situ formation of pure nanocrystalline ZnS deposits at low temperature from complex groundwater solutions by SRB biofilms has been documented (Labrenz et al., 2000; Labrenz and Banfield, 2004; Moreau et al., 2004). Druschel et al. (2002) modeled the source-to-sink geochemistry of this modern ZnS-forming system and reviewed the relevance of the findings to ZnS ore deposit formation. Aggregation of those 1–5 nm sphalerite and wurtzite crystals additionally emphasizes a size-dependent stability shift in sphalerite–wurtzite stability and the role of extracellular proteins in the aggregation of ZnS nanocrystals (Zhang et al., 2003; Moreau et al., 2007). Luther et al. (1999) also showed the importance of zinc-sulfide molecular clusters (particularly Zn_3S_3 and $\text{Zn}_4\text{S}_6^{4-}$) on the speciation of dissolved zinc and their importance in ZnS nanocrystal formation.

Oxidation of ZnS minerals can occur abiotically in the presence of oxygen or other oxidants (Rimstidt et al., 1994), but is oxidized much faster via the activity of oxidizing microbes. Oxidative dissolution of ZnS and other metal sulfides is the principle cause of acid mine drainage (AMD), forming acidic, metal-rich waters (Nordstrom, 2000; Druschel et al., 2004). ZnS mineral oxidation releases dissolved Zn^{2+} ions and associated complexes into aqueous solutions. When AMD waters containing Zn^{2+} are neutralized, zinc can precipitate as a carbonate or oxide form, but is more commonly associated with iron oxide and oxyhydroxide minerals due to sorption of Zn^{2+}

to those mineral surfaces, which can remove the majority of dissolved zinc from solution at circumneutral pH (Jönsson et al., 2006).

Biological effects of Zinc: Zn contamination and bioremediation

As a micronutrient Zn(II) is an ubiquitous essential metal ion playing an important role in organisms throughout the three domains *Bacteria*, *Archaea*, and *Eukarya*. It is essential for numerous physiological processes, serves as a cofactor in members of all six major functional classes of enzymes and is especially important in the maintenance of protein structure (Blencowe and Morby, 2003). In excess it can have toxic effects, but usually Zn deficiency is more critical for most of the higher organisms (Henkin, 1984).

Usually due to anthropogenic activity zinc has been shown to exist at significantly elevated levels in groundwaters and in soil and sediments (Sani et al., 2001). It has repeatedly been demonstrated by cultivation-dependent as well as independent methods that this contamination can have ecotoxicological effects on, e.g., soil microorganisms, and can change the microbial community composition and activity (Hanbo et al., 2004; Smolders et al., 2004). Unfortunately, critical thresholds for toxic effects of Zn on microorganisms are not easy to develop because these can be influenced by the exposure time of Zn to the environment (Mertens et al., 2006) and the potential adaptation of microbial populations to changing Zn concentrations over time.

Great interest in Zn–microbe interactions has arisen in recent years as scientists and engineers try to remove, recover, or stabilize Zn in soils, contaminated water, or waste streams (Sani et al., 2001). In general, specific metabolic pathways leading to precipitation of heavy metals as metal sulfides, phosphates, or carbonates possess significance for possible biotechnology applications (Kotrba and Ruml, 2000) and, analogous to their potential role in low-temperature Zn ore deposition, SRB are already commonly used for the bioremediation of metal-contaminated soil or water. White et al. (1998), for instance, described an integrated microbial process for the bioremediation of soil contaminated with toxic metals using microbially catalyzed reactions. In this process, bioleaching of Cd, Co, Cr, Cu, Mn, Ni, and Zn via sulfuric acid produced by sulfur-oxidizing bacteria was followed by precipitation of the leached metals as insoluble sulfides by the action of SRB.

Conclusion

Zinc is a common element throughout the world, mainly concentrated in zinc sulfide deposits, and has an important biological role as an essential metal ion in organisms of all three kingdoms. Though microorganisms do not directly metabolize forms of zinc, the mobility and in part the deposition of Zn^{2+} as ZnS minerals is strongly dependent on the activity of sulfur-reducing and sulfur-oxidizing microorganisms. Indications exist for the active

involvement of ancient sulfate-reducing bacteria in the genesis of low-temperature Zinc ore deposits and a potential biosignature capacity of nanocrystalline sphalerite for this process; however, these aspects will need further investigation.

ICHOLOGY

Murray K. Gingras, Kurt O. Konhauser
University of Alberta, Edmonton, Alberta, Canada

Definition

Ichnology is the study of fossilized, generally macroscopic, animal–sediment interactions. This includes morphological, textural, and local compositional effects related to the animal’s activities. Similar studies in modern sediments are referred to as neoichnology.

Overview

Ichnological studies comprise a wide range of animal–sediment interactions. The scope of animal–sediment interactions was broadly established by Seilacher (1967). He showed that various animal activities, including motility, dwelling, grazing, farming, scavenging, predation, and sessile feeding, are represented by ichnofossils (also referred to as trace fossils).

Bioturbation is the displacement of sediment by animals. In marine environments, common mediators of bioturbation include worm-form animals (such as nemerteans, polychaetes, and hemichordates), marine crustaceans, bivalves, motile echinoderms, sponges, and sea anemones.

Ichnofossils can form from impressions on the sediment surface, intrusion into the sediment, or from excavation of sediment. The former can be thought of as tracks and trails, whereas intrusions and excavations are generally represented by burrows, shafts, and tunnels. Biodeformation structures may result from intrusive activities in loose or fluid-rich sediment. Intrusive, excavatory, and biodeformational structures impact the sedimentary and geochemical character of the surrounding sediment. Traces also incorporate, rework, and redistribute organics

in sediment. This influences the geochemical zonations associated with sedimentary surfaces, and in this regard, bioturbation can be viewed as a diagenetic process.

Biomechanical alteration of sediment texture

Burrowing organisms significantly alter the physical character of a substrate. The changes involved include redistribution of grain sizes (vertically and laterally), modification of grain size, sediment compaction, and sorting (summarized in Bromley, 1996). The physical manifestations of bioturbation are variable depending on the intrusive process employed by the animal (i.e., inversion, compression, excavation, or backfill).

In clastic sediments, the most important result of bioturbation is the rearrangement of coarse *versus* fine grains. This results in an alteration of permeable pathways in the sedimentary media that can influence diagenetic reactions. In carbonate sediment, grain-size reduction probably represents the most significant substrate modification (Chow and Longstaffe, 1995). Reduction of substrate grain size permits a larger surface area to interact with diagenetic fluids and provides more nucleation sites in a given volume.

Biochemical alteration of sediment texture

An important result of bioturbation is the incorporation of localized, concentrated organic material in the form of mucus or feces. Burrow-associated organics induce a geochemical microenvironment that may extend several centimeters, or even decimeters, into the substrate. In well-aerated sediments, burrow linings comprising agglutinated, fecal or primary organic material contain the most concentrated local sources of organic material. These burrows therefore provide excellent substrates for bacterial colonization. Grazing and mining of intact organic remains further lead to their disintegration and introduce larger surface areas for microbial respiration. Moreover,

the ingestion of refractory organic carbon can lead to the excretion of more labile fecal pellets (Lee, 1992).

With most intrusive bioturbation, the sediment–water interface increases in surface area as a result of infaunal animal colonization. The larger (and deepened) sediment–water interface alters chemical fluxes between the sediment and water column. Animals that pump water through their burrow (bioirrigation) increase the rate of chemical flux. Most notably, irrigation of worm burrows with oxygenated seawater results in increased downward and lateral diffusion of O₂, which then affects the oxidation of redox-sensitive elements. For the aforementioned reasons, the accepted scheme of biogeochemical zones in sediment is an oversimplification. Bioturbation influences the solid phase and pore-water properties of sediment by increasing the transport of diagenetic reactants and products across the sediment–water interface. Consequently, surficial sediments cannot be considered a homogeneous medium characterized by one-dimensional vertical diffusion. They are, instead, heterogeneous and intensively mixed with a complex spatial distribution of biogeochemical zones that are difficult to accurately resolve (Aller, 1980).

Metal ion enrichment in ichnofossils

Cation enrichment in burrow linings is the result of sorptive processes. Metals concentrate in burrow linings in three ways: (1) adsorption, as oxide or oxyhydroxide coatings on to the high-energy surfaces provided by fine-grained particles (silt and clay); (2) as sulfide or phosphate phases under reducing conditions; or (3) associated with organic material (as adsorbed coatings or forming organo-metallic complexes) (Over, 1990). The relative importance of each type of enrichment mechanism varies with the depth of burrow penetration, the grain size/composition of the sediment, and bottom-water and pore-water composition.

Ichnofossils and cementation

Trace fossils commonly influence local cementation patterns by changing the sediment texture, its redistribution, and local composition (Gingras et al., 2004). They also facilitate the accumulation of microbial communities, and through their chemoheterotrophic metabolisms, the microbes can alter pore-water chemistry and saturation states. Ichnofossils also possess higher metal concentrations which can serve as nucleation sites for authigenic mineral formation. Although ichnofossils have been strongly linked to the distribution of microorganisms, there is no existing model associating trace fossil diagenesis to microorganic process.

Summary

The presence of ichnofossils/bioturbation in a sedimentary substrate has the effect of altering sediment distribution and permeability pathways. Moreover, the redistribution and stowage of organics in and around

ichnofossils strongly influence the distribution of microorganisms associated with the sedimentary surface. This has an impact on the nature and distribution of biochemical zonations in sediment. The mechanical and (bio)chemical nature of trace fossils influences diagenetic processes.

MICROBIAL SURFACE REACTIVITY

David A. Fowle, Kurt O. Konhauser
 University of Alberta, Edmonton, Alberta, Canada

Definition

The chemical charge on a cell surface caused by the deprotonation/protonation of organic functional groups.

Overview

Similar to an aqueous organic acid, bacterial cell surfaces can either bind or release protons (H^+) into solution depending upon the solution pH. In the case of the latter, this deprotonation process, which accurately mimics a number of the functional groups associated with cell surfaces, leads to the formation of an organic anion, or ligand. Unlike an aqueous organic acid, which exhibits proton buffering over a narrow pH range (± 1 –2 units), bacterial cell walls have continuous buffering capacity over a wide range of pH values which span most geologic settings (pH 2–10). Ultimately, most surface reactivity of bacteria with its external environment results from the enhanced electronegativity of the cell wall as these functional groups deprotonate. In its most simplistic form, deprotonation can be expressed by the following equilibrium reaction:

where B denotes a bacterium to which each protonated ligand type, A, is attached. The distribution of protonated and deprotonated sites can be quantified with the corresponding mass action equation:

$$K_a = \frac{[B - A^{-1}][H^+]}{[B - AH^0]}, \quad (2)$$

where K_a is the dissociation constant; $[B - A^{-1}]$ and $[B - AH^0]$ represent the concentration of exposed deprotonated and protonated ligands on the bacterium, respectively (in mol l^{-1}); and $[H^+]$ represents the activity of protons in solution. Each functional group has its own K_a , and based on equation (2), the pH at which $[B - A^{-1}]$ and $[B - AH]$ are equivalent is known as the pK_a value, where $pK_a = -\log_{10} K_a$. At $pH < pK_a$ surfaces are protonated and at $pH > pK_a$ they are deprotonated.

The ionization of functional groups provides an electrical charge ($[L]_T$ represented in mol mg^{-1}), which in the laboratory can be calculated as a function of pH from the difference between total base or acid added to a suspension of organic material and the equilibrium H^+ and OH^- ion activities (Reaction 3):

$$[L]_T = \frac{C_a - C_b \pm [OH^-] - [H^+]}{S} \quad (3)$$

Microbial Surface Reactivity, Figure 1 Experimental data demonstrating the buffering capacity of *Bacillus subtilis* during acid–base titration (circles; molality of protons added normalized with respect to the wet weight of bacteria present) and zeta potential (diamonds) gathered from titrations of *Bacillus subtilis* in 0.01 M NaNO₃ that were cultured in tryptocase soy broth.

The components, C_a and C_b , are the concentrations of acid and base added, respectively; n_{OH^-} and n_{H^+} are the number of moles of OH^- and H^+ in the solution at the measured pH, respectively; while “S” is the quantity of the solid (usually expressed in dry weight, i.e., mg). When such calculations are done over an entire pH range, an acid–base titration curve is created that shows the pH range over which some functional groups are chemically active and how the net surface charge of the organic surface varies with pH (Figure 1). A large difference in the total base or acid added and the free H^+ ion activity indicates significant pH buffering and a high concentration of surface functional groups. On the titration curve this is shown by a steep slope. A small difference in the total base or acid added and the free H^+ ion activity indicates weak pH buffering and a low concentration of surface functional groups. This translates into a gentle slope on a titration curve. In terms of microbial biomass, carboxyl groups account for the buffering capacity from pH 2–6 (Reaction 4), phosphate groups from pH 5–8 (Reaction 5), amino groups at pH > 8 (Reaction 6), and hydroxy groups deprotonate at pH values above 10 (Reaction 7) (see Konhauser, 2007).

As a consequence of the deprotonation reactions, the microbial surface develops an electrical charge. Therefore, when subjected to an electric field, microorganisms move in the direction, and at a rate, commensurate with the polarity and density of the overall surface charge. This process is termed electrophoresis, and the electrophoretic mobility of a microbial suspension can be quantified by measuring their velocity in an electric field. This measurement can, in turn, be used to calculate the zeta potential (ζ), using the Smoluchowski equation below (Hunter, 2001):

$$\zeta = \frac{\eta \mu}{\epsilon_0 \epsilon} \quad (8)$$

The component “ μ ” is the electrophoretic mobility of a particle; ϵ_0 and ϵ are the relative dielectric constants of the vacuum and solution, respectively; and η is the viscosity of the solution. The zeta potential reflects the electrical potential at the interfacial region (viewed as a shear plane) separating an inner layer, where cations are held tightly in place and move with the bacterium, and an outer layer where ions are mobile (Wilson et al., 2001). The greater the absolute value of the ζ potential, the greater the charge

density on the surface (Blake et al., 1994). The electrophoretic mobility (and zeta potential) is pH dependent because the activity of protons in solution controls the ionization reactions of functional groups at the microbial surface (Ahimou et al., 2001) (Figure 1). This leads us to the concept of isoelectric point, which is defined as the pH value where the net surface charge of a solid is zero. The isoelectric point can be estimated from acid–base titrations, but it can also be directly measured with electrophoretic mobility experiments because at the isoelectric point microbes do not exhibit motion in an electric field. The isoelectric point of bacterial cell walls is typically between pH 2–4 (Harden and Harris, 1953). This means that at low pH, when the surface functional groups are fully protonated, bacteria are either neutral or positively-charged, the latter being the result of a cell possessing abundant amino groups. Meanwhile, at the growth pH of most bacteria, cells inherently display a net negative charge and the magnitude of negativity increases with higher pH values. As a result, under low pH conditions, most bacterial surfaces behave hydrophobically, but with an increasingly hydrophilic nature with increasing pH.

One of the major challenges faced by the researchers today is how to translate acid–base titration data in terms of cell wall biochemistry. Ascribing pK_a values from a titration curve to specific functional groups can be problematic because there is often significant variation in pK_a values for the same functional group. This occurs because the magnitude of the dissociation constant is controlled by the structure of the molecule to which it is attached (see Martell and Smith, 1977 for details). Consequently, a single carboxyl group in two different organic acids will have different pK_a values, as will an organic acid with multiple carboxylic groups. As might then be expected, the pK_a for a carboxyl group on one microbial species versus another could yield widely different values simply because of subtle conformational variations within the wall macromolecules. Furthermore, titration experiments are only able to resolve those groups that contribute significant amounts of protons to solution. Minor groups are simply undetectable with the resolution of current techniques. It is thus important to keep in mind that the model-derived binding sites do not directly represent the functional groups of the cell surface; their identity can only be inferred by comparison of the functional group pK_a values with pK_a values of model compounds. Unequivocal identification of the types of functional groups responsible for acid–base buffering may be obtained by spectroscopic techniques, such as Fourier transform infrared spectroscopy (FTIR), calorimetry or gas/liquid chromatography of cell wall extracts. For instance, Yee et al. (2004) and Jiang et al. (2004) used infrared spectroscopy to examine the pH dependence of deprotonation of bacterial cell-wall functional groups. Although not all pH conditions were studied, it was clear that the vibrational frequencies of carboxyl type groups increased with increasing pH. Calorimetric measurements of protonation reactions on bacterial surfaces indicate

these reactions are exothermic with relatively small site-specific entropies (Gorman-Lewis et al., 2006). This provides more evidence that (1) hydrogen bonding between protonated and deprotonated sites likely stabilizes the cell wall, and (2) bacterial cell wall functionalities are similar to multifunctional organic acids rather than simple organic acids.

Summary

Microbial surface reactivity results from the protonation and deprotonation of the organic moieties of microbial cell surfaces including carboxyl, phosphate, amino, and potentially hydroxyl groups. These groups behave similarly to multifunctional organic acids – they hydrogen bond with each other which leads to negative charge on the cell wall as pH increases. At most environmentally relevant pH values, microbial cell surfaces will possess a net negative charge, and therefore, will interact with positively charged cations or mineral surfaces.

WHALE AND WOOD FALLS

Steffen Kiel
 University of Göttingen, Göttingen, Germany

Synonyms

Biogenic substrates; Food falls; Nekton falls; Organic falls; Sunken wood

Definition

Whale fall: Carcass of a large marine mammal of the order Cetacea (whales) that has sunken to the seafloor.

Wood fall: A piece of wood that has sunken to the seafloor.

History

The first examples of specialized invertebrates inhabiting bones and wood in the *deep sea* (qv) were recognized during the deep-sea expeditions in the early to mid 1900s. Because these samples were recovered by dredging, the complexity of whale- and wood-fall ecosystems was not recognized before the advent of deep-sea research vessels. Pioneering experimental work on wood-falls was carried out in the early 1970s by Ruth Turner (1914–2000), using the deep-sea research vessel *Alvin*. This research came to a halt in the late 1970s when deep-sea *hydrothermal vent systems* (qv) and their fascinating fauna were discovered and *Alvin* was occupied by exploring these systems. The first deep-sea whale-fall ecosystem was accidentally discovered by Craig Smith during an *Alvin* dive in 1987 and consisted of a whale skeleton associated with many chemosymbiotic taxa that were also known from hydrothermal vents (Smith et al., 1989). Nowadays, whale-fall ecosystems are mainly investigated by sinking stranded whales which are then studied by submersibles and/or ROVs. The last major discovery in this field was *Osedax*, a “bone-eating” siboglinid worm living in symbiosis with bacteria that degrade bone lipids and cartilage (Rouse et al., 2004).

Bivalve-bored wood has been known from the fossil record for centuries, but reports on other invertebrate groups that utilized wood falls in the geologic past are rare, and entire fossil wood-fall ecosystems have only been described very recently (Kiel and Goedert, 2006b; Kiel et al., 2009). Fossil examples of deep-sea whale-fall ecosystems were discovered soon after the discovery of the modern ones and are especially common in uplifted deep-water sediments around the North Pacific margin (Squires et al., 1991; Kiel and Goedert, 2006a). Similar ecosystems were recently found on two late Cretaceous plesiosaur (a marine reptile) skeletons in Japan (Kaim et al., 2008).

Whale falls

Whale falls are the basis for the most species-rich deep-sea ecosystem, with more than 400 species known to date (Baco and Smith, 2003). Whale falls pass through three ecologic stages that vary in length and can overlap. At first the flesh of the whale carcass is removed by sleeper sharks, hagfish, and other scavenging deep-sea fishes. In the second stage small annelids and crustaceans consume the remaining particulate organic matter. The main source of nutrients during the third stage is the hydrogen sulfide (H₂S) generated by the anaerobic decay of bone lipids, which is utilized by species harboring chemotrophic endosymbionts or by species that graze on sulfur-oxidizing

bacteria (Smith and Baco, 2003). While this “sulfophilic stage” can last up to 100 years in oxygen-poor ocean basins, it can be as short as a few years in areas where *Osedax* rapidly consumes and destroys the bones (Braby et al., 2007; Fujiwara et al., 2007).

Whale bones consist of up to 65 wt% of lipids. These lipids are consumed by *sulfate-reducing bacteria* (qv) at the oxic–anoxic interface in the bone, using seawater as sulfate source and emitting H_2S as metabolic byproduct. This H_2S is then consumed by *Beggiatoa* (qv) and other sulfur-oxidizing bacteria on the surface of the skeleton (Figures 1 and 2). Bone lipids and other whale remains entering the, or covered by, sediment are also consumed in this way. The resulting H_2S is either consumed by bacterial mats surrounding the whale carcass, or by invertebrates harboring sulfur oxidizing bacteria. These invertebrates include siboglinid tube worms, solemyid,

Whale and Wood Falls, Figure 1 Whale skeleton in the deep sea, covered by a large bacterial mat; photo by Craig R. Smith.

Whale and Wood Falls, Figure 2 Generalized geobiologic processes at whale falls. (Modified from Smith and Baco, 2003.)

lucinid, and vesicomyid clams, and bathymodiolin mussels. Bacteria-grazing taxa include provannid, limpet-like and various other small-sized gastropods (“skeneimorphs”), and polynoid annelids (Smith and Baco, 2003).

Fossil whale fall communities are known from to Pliocene sediments. They preserve mollusk associations resembling those at modern whale falls, and fossil traces of *Osedax* (Kiel et al., 2010).

Wood falls

Wood falls in the deep sea support complex ecosystem of 40 or more invertebrate species, some of which are endemic to this habitat. The wood is utilized by several xylophagous (wood-eating) invertebrate groups. Most important are wood-boring bivalves of the heterodont families Teredinidae (also known as shipworms; mainly in shallow water) and Xylophaginae (mainly in deep water below 100 m) which rapidly consume and destroy the wood, presumably aided by cellulolytic symbiotic bacteria (Turner, 1973; Distel and Roberts, 1997). Shallow water wood falls are also utilized by wood-boring isopods of the family Limnoriidae. In deeper water exists a small number of xylophagous gastropod limpets and chitons (polyplacophorans), which are preyed upon by gastropods, annelids, and crustaceans. The microbial fauna on wood falls consists of a variety of fungi and bacteria (Kohlmeyer and Kohlmeyer, 1979; Palacios et al., 2006) and these microbes are grazed upon by gastropods and chitons. Chemosymbiotic species which are phylogenetically related to those at whale falls are also found on sunken wood. They probably rely on sulfide from the anaerobic decay of fecal pellets of the shipworms, or from the decaying wood itself (Figures 3 and 4; Kiel and Goedert, 2006b; Pailleret et al., 2007). The fossil record of deep-sea wood-fall communities extends back into the late Cretaceous.

Summary

Whale and wood falls in the deep sea harbor species-rich ecosystems that rely to a certain extent on H_2S from the decay of the bones and the wood. Many of the species inhabiting these habitats are endemic. Especially the chemosymbiotic and bacteria-grazing taxa are phylogenetically related to those living at *hydrothermal vents* (qv) and *cold seeps* (qv). The main H_2S source for the chemosymbiotic taxa at whale falls is the anaerobic breakdown of bone lipids by sulfate-reducing bacteria. In the case of the wood falls, it is the anaerobic decay of excrements of wood-boring bivalves (Xylophaginae). Wood-fall communities with a fauna that is taxonomically comparable to the modern wood-fall fauna are known from the late Cretaceous. Whale-fall communities are as old as ocean-going whales (late Eocene). Similar ecosystems with bacteria-grazing gastropods on plesiosaur bones are known from the late Cretaceous.

deposition of this material to the sediments. Furthermore, input of nutrients to the global coastal ocean region have also significantly increased, which may stimulate increased production of organic matter and subsequent deposition of this material to the sediments within this region. As long as surface seawaters are supersaturated with respect to most carbonate phases, microbial decomposition of organic material is the main driver of carbonate dissolution. Consequently, even if the organic material deposited to the sediment–water remained constant, but the microbial activity increased, for example, owing to increasing temperature, carbonate dissolution would also increase. For the next several decades, human activities are likely to continue to lead to acidification of surface seawater and continuous increases in the amount of organic material being deposited to shallow-water sediments, and concurrently with increasing atmospheric concentrations of CO₂, surface and sea surface temperatures are likely to increase with potential increases in microbial and endolithic activity. As a result, dissolution of calcium carbonate minerals, particularly in coastal ocean environments, probably will increase due to all of these forcings. It is possible that under a business as usual scenario of fossil fuel CO₂ emissions, the production of carbonates in the global coastal ocean will be exceeded by their dissolution by year 2150 or earlier.

Summary

Diagenesis refers to those physical, chemical and biological processes that alter the original physical and chemical characteristics and properties of minerals and sediments. Calcium carbonate minerals constitute a substantial fraction of shallow-water sediments and may be subject to significant diagenetic alterations after deposition including dissolution and precipitation reactions. These reactions are largely mediated by microbial processes including oxidation of organic matter under both oxic and anoxic conditions as well as by endoliths, which actively penetrate carbonate substrates. The extent of calcium carbonate dissolution is to a large degree controlled by the amount of organic matter decomposed. Carbonate dissolution is likely to increase in the future in response to human-induced ocean acidification arising from the burning of fossil fuels, but also due to increased riverine transport of organic matter and nutrients to the coastal ocean, enhanced production in situ of organic matter in coastal waters, and subsequent deposition and microbial decomposition of the organic matter in marine sediments.

BIOLOGICAL VOLCANIC ROCK WEATHERING

Charles S. Cockell
 Open University, Milton Keynes, UK

Definition

The biologically induced breakdown of volcanic rocks, including crystalline rocks and glasses.

Volcanic rock weathering and global processes

The weathering of volcanic minerals is known to make a significant contribution to the global silicate weathering budget (Dessert et al., 2003), thus influencing carbon dioxide drawdown and climate control, since carbon

dioxide is consumed in mineral weathering reactions. For example, on land, the Deccan Traps in India, with an estimated area of 10^6 km², is thought to account for about 5% of the global silicate weathering flux (Dessert et al., 2003). In total, basalt rocks may account for over 30% of the global carbon dioxide drawdown in silicate weathering (Gaillardet et al., 1999). The weathering of volcanic rocks also contributes a significant flux of nutrients into the biosphere, and through the weathering of rocks and the formation of clays and secondary minerals, microorganisms accelerate the rate of production of volcanic soils (Andisols) from their parent minerals. Thus, understanding how volcanic rocks weather and what role a biota might play in these processes has importance for understanding climate control, soil formation, and the mechanisms governing the release and distribution of nutrients in the biosphere.

The biological role

The role of plants in accelerating the weathering of volcanic rocks has been established, primarily from studies in Hawaii and Iceland. In Hawaii, plants have been estimated to increase weathering rates by over an order of magnitude compared to unvegetated areas (Cochran and Berner, 1996). In geological terms, the acceleration of weathering caused by plants following their early evolution has been proposed as one mechanism for carbon dioxide drawdown in the late Silurian, resulting in a general cooling trend (Berner, 1992). Plants increase weathering rates by, *inter alia*, physically disaggregating the rock with their roots, the production of rock weathering organic acids, the removal of ions from the subsurface (which changes chemical equilibrium in favor of rock dissolution), and by indirectly producing nutrients and favorable microenvironments for prokaryotes and fungi within the rhizosphere, which themselves weather rocks (see below).

A microbiological involvement in volcanic rock weathering has been established. The primary effect of microorganisms is to accelerate the breakdown of the rock both physically and chemically, often with the formation of secondary minerals such as poorly ordered aluminosilicates and clays (Figure 1). Early studies on the biological weathering of volcanic rocks focused on the role of lichens (Jackson and Keller, 1970; Adamo and Violante, 1991, 2000; Banfield et al., 1999). The earliest study of biological volcanic rock weathering was the seminal study by Fry (1927) who showed that lichens can cause etching, fragmentation, and weakening of obsidian, a silica-rich volcanic glass. Lichens accelerate the physical disaggregation of volcanic rocks as the lichen thallus penetrates the rock substrate. The production of organic acids, organic complexing agents, and the excretion of oxalic acids are just some of the mechanisms by which lichens contribute to the chemical dissolution of the rock substrate (Adamo and Violante, 2000). Oxalic acids are produced by the fungal component in the lichen symbiosis. Calcium oxalate at the lichen–rock interface, although not

Biological Volcanic Rock Weathering, Figure 1 A 1913 basalt flow in Iceland covered in lichens, which play an important role in rock weathering. Image is 20 cm across.

ubiquitous, is one widely reported compound formed on lichen-weathered rocks, which suggests the role of oxalic acids reacting with mineral-derived calcium, although other oxalates, such as copper- and manganese-rich compounds, have been reported.

Lichens have been shown to induce the formation of considerably thicker weathering rinds on crystalline basalts in Hawaii compared to control rocks, which in addition to directly contributing to weathering, may secondarily accelerate the rate of abiotic chemical weathering (Jackson and Keller, 1970). Lichens may also accelerate the dissolution of the silicate from the rock matrix, causing it to be more susceptible to being washed away, promoting the preferential formation of oxides and other secondary minerals from iron. Iron oxide formation is reported at the interface between lichens and basaltic rocks in Hawaii and near Vesuvius, Italy.

Early studies on lichen weathering of volcanic rocks were the first to elucidate two important factors in microbial rock weathering in general: (1) the role of changes in the microenvironment induced by microorganisms at the rock surface, which include changes in pH, water retention, and redox state that alter the equilibrium chemistry of rock dissolution or secondary mineral formation, accelerating rock weathering; and (2) the differential susceptibility of minerals to microbial rock weathering. Calcium-containing plagioclase tends to weather faster than minerals, such as K-feldspars, and these differential effects are determined by the susceptibility of minerals to weathering agents produced by microorganisms or the changes in chemical equilibria.

Since early studies on lichens, many other microorganisms have been examined and found to be capable of accelerating rock weathering. Mechanisms of microbial weathering include: the production of organic acids; the secretion of protons, which changes the local pH at the

rock surface and accelerates weathering; and the production of complexing ligands, such as siderophores, which chelate oxidized iron. It is also becoming clear that these are not merely serendipitous processes resulting from microbial metabolic activity, but that microorganisms actively excrete substances to gain access to nutrients within rocks that might otherwise be limiting, such as major nutrients, including Fe, P, Na, and Ca and trace elements such as K, Ni, or Mn. In addition to the secretion of weathering-promoting substances, by oxidizing or reducing metals during energy acquisition microorganisms can accelerate chemical dissolution or alteration of the rock surface, particularly important examples being iron-oxidizing or reducing bacteria, which use iron as an electron donor or acceptor respectively, and may therefore change the oxidation state of the iron in iron-containing minerals, including olivines and pyroxenes, which form an important component of basaltic mineralogies.

The considerations above apply to both fungi and prokaryotes. In the case of fungi, the penetration of the rock by the hyphae is one primary means by which fungi can invade the interior of a rock and accelerate weathering. Fungi, in particular, are well-known to produce organic acids by which they contribute to rock weathering (Mehta et al., 1978; Gadd, 2006).

Microorganisms do not merely accelerate the weathering of all elements from volcanic rocks. A number of studies have shown that biotic weathering can cause preferential leaching or enrichment of elements at the weathering front or within the sediments produced by volcanic rock weathering. Staudigel et al. (1998), in a study of basaltic glass weathering using a microbial enrichment culture from Loihi seamount, Hawaii, showed that the population of microorganisms, which included heterotrophic bacteria, cyanobacteria, and diatoms, induced an enrichment of calcium in the sediments produced by weathering, but a loss of magnesium, in contrast to the controls which showed the opposite trend. These results, and many others, show that microorganisms can cause a differential rate of leaching of different elements from rocks. Bacteria on their own have been shown to induce the release of iron and manganese. Investigations using a single bacterial species (*Burkholderia fungorum*) (Wu et al., 2007) showed that iron release is induced by changes in the pH at the rock surface. Phosphorus released from the apatite within the basalt rock apparently also helped sustain bacterial growth. All of these experiments show that microorganisms potentially have an important role in modulating the release of different elements from the crust. The oxidation of iron by bacteria in the deep-sea probably gives them an important role in iron cycling and thus weathering of the basalt crust (Edwards et al., 2003).

These data also highlight the general point that although the role of microorganisms in enhancing mineral dissolution has been a major focus of research, it is also important to understand that the weathering of elements from rocks might be influenced by the retardation of elemental release caused by microbial action. For example,

the production of oxidized iron from reduced iron in basaltic minerals such as olivine has been suggested to retard leaching of elements from the rocks (Santelli et al., 2001). Thus, through changes in oxidation states of elements and the production of secondary minerals at rock surfaces, the microbial involvement in volcanic rock weathering may be much more complex than merely enhancing weathering rates, instead changing the leaching rates of specific elements in ways that are either retarded or accelerated compared to abiotic conditions.

The formation of clays and poorly ordered aluminosilicates, such as smectites and allophane-like materials, has been reported around bacterial aggregates in volcanic ash near Sakurajima volcano, Japan (Kawano and Tomita, 2001). The authors, by carrying out batch culture experiments in the laboratory using bacteria isolated from the ash, suggest that the natural populations are involved in biomineralization and therefore play an important part in bacterial alteration of the weathered volcanic ash. In this case mineral formation is likely to have been facilitated by the bacterial cell surface. Although this work did not show active weathering of the primary rock minerals, it illustrates that the formation of clays and other minerals from weathered volcanic ash by microorganisms can play an important role in defining the chemical characteristics of the weathering environment, which itself will alter the environment for other members of the microbial community which may be directly involved in weathering. The work underlines the important link between rock weathering (dissolution and alteration) and mineral formation (biomineralization) during the transition of primary volcanic minerals to soils such that both processes must be considered to truly understand biological volcanic rock weathering and soil neogenesis.

As a logical development of the work of Fry, Herrera et al. (2008) examined bacterial communities within obsidian in Iceland and showed a diverse population of bacteria, which by the use of hybridization probes were shown to be associated with weathering alteration fronts in the rock. Basaltic rocks in terrestrial environments, as with the oceanic environments described above, have been shown to harbor a high prokaryotic diversity (Gomez-Alvarez et al., 2007).

The mechanisms by which microorganisms weather rocks are still based primarily on chemical measurements such as organic acid production or changes in solution pH. New molecular methods are likely to elucidate pathways by which microorganisms can weather rocks and strengthen our understanding of the link between the organisms and the weathering process.

Microbial borings in volcanic glass

Other evidence for a direct role of microorganisms in volcanic rock weathering has been presented in the form of channels or pitted and corroded granular textures, in reactive volcanic glasses. The most commonly studied of these are endolithic borings into volcanic glasses, including

Biological Volcanic Rock Weathering, Figure 2 (a) An outcrop of subglacial basalt glass at Valafell, Iceland. The glass turns conspicuous brown as it transforms into palagonite, a weathering product, (b) “elongate” (tunnellike) weathering features in a vesicle within the outcrop, features (arrow) are at the interface between the palagonite weathering rind (center) and the glass (scale bar 40 μm). The biological origin of such features in different environments is an ongoing controversy.

deep ocean pillow lavas (Fisk et al., 1998; Torsvik et al., 1998; Thorseth et al., 2003; Storrie-Lombardi and Fisk, 2004). Furnes and Staudigel (1999) suggest a dominant role for bioalteration of volcanic glasses in the upper 300 m of oceanic crust. Glass recovered by drilling from more than 250 m below the sea floor shows channels into altered zones that are 1–10 μm wide and penetrate to a depth of 150 μm . In other settings, larger tubes up to 20 μm in diameter and with a depth of 0.5 mm have been observed. The provenance of some of these borings has been controversial since the organisms responsible for the borings have not been cultured. Abiotic ambient inclusion trails, generated by the pressure forcing of mineral grains, such as sulfides, through glass have been suggested as a mechanism for the production of channel features (Figure 2). To address this possibility a number of approaches have been used to show an involvement of biological activity. These include isotopic and elemental analysis. Binding of the nucleic acid stain DAPI (4',6-diamidino-2-phenylindole) to DNA and fluorescence signals obtained using fluorescent in situ hybridization (FISH) probes against both archaea and bacteria in the channels suggest that organisms were responsible for the weathering. Microprobe analysis shows the presence of carbon not associated with carbonates. Low carbon isotope values were also suggested as evidence supporting a biological role in glass alteration.

Early Earth studies and astrobiology

Volcanic terrains would have dominated the landscape of the Archean Earth when life emerged about 3.5 billion years ago. One reason for the keen interest in weathering textures in volcanic glass is the discovery of similar features in ancient Archean volcanic rocks (Furnes et al., 2004). Insofar as channels are morphologically more distinctive than, for example, irregular pitted features, then they might offer evidence for life in early Earth environments. The age dating of materials with biological isotopic signatures has been used to argue that fossils of putative

ancient microbial volcanic glass borers are the same as the age of the rocks (Banerjee et al., 2006). The study of microbial volcanic rock weathering and the textures and minerals left by such interactions may also offer a means to assay ancient Martian terrains for evidence of life (McLoughlin et al., 2007), particularly since Mars, in the absence of plate tectonics, is a planet dominated by volcanic terrains. On a more general level, understanding the interaction of microorganisms with volcanic rocks may provide a means to understand whether the formation of clays and other secondary minerals from basalts on Mars is a purely abiotic process or whether it could ever have been biologically mediated.

Conclusion

Both field and laboratory observations show that plants and microorganisms play an important role in volcanic weathering. The mechanisms by which they achieve this are diverse, but reduce to some common principles which include physical disruption, production of compounds that attack minerals, alteration of chemical equilibria in favor of dissolution, and changes in redox states of metals which favors dissolution. Through their actions, the biota generally accelerates rock weathering, contributing to the release of rock nutrients into the environment and silicate weathering reactions which themselves contribute to long-term carbon dioxide drawdown.

Definition

Biomarkers are the molecular fossils of lipids and other natural products. In sedimentary environments, lipids that escape the remineralization process are commonly chemically reduced to hydrocarbon skeletons. Encased in sedimentary rocks, these skeletons can remain intact over hundreds of millions of years. The structure of biomarkers is often directly related to their precursor lipids and may be diagnostic for a specific group or groups of organisms. Diagnostic biomarkers are used to obtain information about the composition of past (microbial) ecosystems or to determine the first occurrence of organisms in the geological record. As many organisms prefer specific habitats, and as lipid compositions of individual organisms are frequently adjusted to changing physical and chemical conditions, biomarkers may also serve as paleoenvironmental proxies, for example for salinity, temperature, and oxygen availability. In the petroleum industry, biomarkers are utilized to elucidate the extent of biodegradation of crude oil and to obtain information about the thermal history, lithology, depositional environment, and geological age of hydrocarbon source rocks.

METALLOGENIUM

Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

Metallogenium s.str. is a star-shaped enigmatic bacterium oxidizing Mn and iron. It preferentially lives in limnic environments.

Metallogenium is a relatively large (2–10 μ m) microorganism with bacterial affinities that concentrates manganese and iron oxides in significant amounts. The genus *Metallogenium* has not yet been assigned to any taxonomic group. The cells lack rigid walls and develop flexible, tapering threads from which new cells probably arise. The organism is therefore, star-shaped and is found in various facies, predominantly in limnic environments (Figures 1 and 2). The threads are often heavily encrusted with oxides of iron and/or manganese. The oldest

Metallogenium, Figure 1 *Metallogenium personatum*. (Redrawn from Perfil'ev and Gabe, 1961.)

Metallogenium, Figure 2 *Metallogenium personatum*. (Redrawn from Klaveness, 1999.)

Metallogenium-like fabrics are known from the 1.88 Gy old Paleoproterozoic Gunflint Formation (Barghorn and Tyler, 1965).

The first detailed description of *Metallogenium* was carried out by Perfil'ev and Gabe (1961) who called the type species *Metallogenium personatum*. There is an enormous record of publications about this microorganism (Zavarin, 1964a, b; Dubinia, 1970; Schmidt

and Overbeck, 1984), and many speculations have been made about its systematic position, for example, within the Mycoplasmatales (Zavarin and Hirsch, 1974), Chlamydobacteria (Klaveness, 1977), and Hyphomicrobiales (Perfil'ev and Gabe, 1961). Clasen (1969), Schmidt and Overbeck (1984), and Zavarin (1989), suggested a relationship with the iron bacterium *Leptothrix echinata* (Beger, 1935) which shows a considerable morphological similarity to *Metallogenium*. Unfortunately, valid molecular biological examinations presently do not exist to clarify the phylogenetic position of this organism, although it is common especially in many freshwater lakes (e.g., Klaveness, 1999; Schulte, 1994). Besides *Metallogenium personatum*, which is undoubtedly a prokaryotic organism, "*Metallogenium symbioticum*" was described (Zavarin, 1964b), which is also an Mn-oxidizing prokaryote preferentially growing on fungal microorganisms (Schweisfurth, 1971).

METALS, ACQUISITION BY MARINE BACTERIA

Alison Butler, Vanessa V. Homann
 University of California, Santa Barbara, CA, USA

Definition

Oceanic bacteria produce siderophores to acquire iron. Given that the iron concentration in surface ocean water is very low, siderophores produced by marine bacteria are tailored to the physical and chemical constraints of the marine environment.

Introduction

Microbial iron uptake

Virtually, all bacteria require iron for growth. Bacteria growing under aerobic conditions utilize a variety of pathways to acquire iron, but under conditions of iron starvation, bacteria often produce siderophores (Crosa et al., 2004). Siderophores are low molecular weight, chelating compounds produced by bacteria to facilitate iron(III) uptake (Crosa et al., 2004; Kraemer et al., 2005; Butler, 2007). The Fe(III)-siderophore complex is recognized by a specific outer membrane protein receptor, which catalyzes the transport of the Fe(III)-siderophore complex across the outer membrane (Figure 1).

The study of marine microbial siderophores is relatively new (Butler and Martin, 2005), yet certain characteristic structural features have already begun to emerge: suites of amphiphilic siderophores and photoreactive Fe(III)-siderophores.

Marine Siderophores

Amphiphilic marine siderophores

One characteristic of marine siderophores is the predominance of suites of amphiphilic siderophores, comprised of a hydrophilic head group, which coordinates with Fe(III), and one of a series of hydrophobic fatty acid appendages, which confers amphiphilicity (Figure 2). Two types of suites of amphiphilic siderophores are produced by marine bacteria. The aquachelins, marinobactins, and amphibactins are amphiphilic peptidic siderophores produced by distinct genera of marine bacteria (Figure 2) (Martinez et al., 2000, 2003). The relative amphiphilicity of each of these siderophores is

Metals, Acquisition by Marine Bacteria, Figure 1 Siderophore-mediated iron uptake by a bacterium.

defined by both the number of amino acids in the peptide fraction, compared to the fatty acid chain length (e.g., C12–C18). The amphibactins with only four amino acids and relatively long C18 fatty acids are the most hydrophobic of the amphiphilic peptide siderophores. As a result, they remain cell associated and are extracted from the bacterial pellet during the isolation process (Martinez et al., 2003). In contrast, the marinobactins and aquachelins, with five and six amino acids in the head group and a predominance of the shorter fatty acids, are more hydrophilic and are thus isolated from the supernatant following centrifugation of the bacterial culture to pellet the cells (Martinez et al., 2000).

The synechobactins and ochrobactins (Figure 2) are different suites of amphiphilic siderophores, in which the head group is based on citric acid, as opposed to a peptide. The head group is thus smaller than in the peptidic amphiphilic siderophores. The fatty acids are also shorter than observed for the peptidic amphiphilic siderophores. Nevertheless, the ochrobactins are quite hydrophobic as a result of two fatty acid appendages; these siderophores remain associated with the bacterial pellet (Martin et al., 2006). The synechobactins, with

Definition

Cyanobacteria are a large and morphologically rather diverse group of photoautotrophic prokaryotes and are classified as a monophyletic phylum within Domain Bacteria. Cyanobacteria share oxygenic photosynthesis with the eukaryotic algae. Cyanobacteria belong to the oldest organisms on earth. Their broad environmental tolerance range makes cyanobacteria well suited to live in habitats of extreme and fluctuating conditions where they can outcompete eukaryotic algae.

Many cyanobacteria have large cells like the eukaryotic algae with which they share the same life-style: Consequently, they are often treated as prokaryotic algae or, formerly, blue-green algae. Some cyanobacteria even form macroscopic colonies from the size of a few millimeters to up to 30 cm (Dodds and Castenholz, 1988). Cyanobacteria occur in a broad variety of forms, from solitary unicells over colony-forming and undifferentiated filamentous types to more complex forms that even display the hallmarks of multicellularity. Photosynthetic cyanobacteria produced earth's first oxygen atmosphere, which fostered the rise of eukaryotes. In addition, ancient cyanobacteria produced massive undersea carbonate deposits, thereby reducing atmospheric carbon dioxide levels and influencing global climate. The first plastids arose from cyanobacteria through a process called primary endosymbiosis (McFadden, 2001; Keeling, 2004; Palmer, 2003; Reyes-Prieto et al., 2007). Modern cyanobacteria are recognized for their ability to occupy diverse aquatic and terrestrial habitats, cyanobacteria produce organic compounds used by other organisms, and they stabilize sediments and soils. Nitrogen-fixing cyanobacteria increase soil and water fertility and foster the growth of certain plants and fungi in symbiotic associations. There is strong evidence that cyanobacteria are the oldest microorganisms performing oxygenic photosynthesis, dating back to about 2.45 billion years (Rasmussen and Willemotte, 2008) and with an evolutionary history stretching over at least 1.5 and possibly 2.7 billion years (Blank, 2004). Cyanobacteria are able to live in some of the most extreme habitats on earth (e.g., Seckbach, 2007 for an overview). The broad environmental tolerance range of cyanobacteria in extreme habitats is in contrast to most other prokaryotic and eukaryotic organisms from extreme environments that occur only within a small window of almost constant conditions. From an evolutionary point of view, it appears that cyanobacteria which are

among the oldest organisms on earth may have been forced by the “modern” eukaryotes to withdraw themselves into habitats of extreme and fluctuating conditions (Whitton, 1992; Bhattacharya et al., 1999).

Cell structure

Unlike most groups of prokaryotes, there is substantial morphological and life history variation within the cyanobacteria (Hayes et al., 2007). Although some cyanobacteria occur as solitary unicells, in most species the cells adhere at each other to form at least pairs of cells (representing the products of a recent cell division, *Synechococcus* Figure 1a) or group of cells are held together to form colonies (e.g., in *Myxosarcina*, Figure 1b). Very common growth forms are filaments (trichomes) where the cells are joined end to end through regular divisions into one plane (Figure 1c–g). Such filaments can be even joined into bundles or can be branched (true-branched, Figure 1b or false-branched, Figure 1d). Many filamentous cyanobacteria produce specialized cells known as heterocytes (formerly heterocysts; Figure 1d and g) that function in nitrogen fixation. Such cyanobacteria are usually capable to produce specialized cells for dormancy, known as akinetes, under adverse environmental conditions. Some filamentous cyanobacteria are capable of gliding, a slow uniform motion on a solid substrate. The gliding occurs by an interaction of slime secretion and certain proteinaceous fibers (Hoiczky, 2000). Cyanobacteria lack sexual reproduction, but gene exchange may be realized through viral transduction by specialized cyanophages (Coleman et al., 2006). The only mode of reproduction is by cell division (binary fission, resulting in two equal-sized cells) or simply by fragmentation of a colony. In unicellular cyanobacteria, baeocytes (endospores) are formed by the division of the cytoplasm several times and in different planes whereby the mother does not increase in size. Filamentous cyanobacteria form hormogonia (Figure 1e), which are short filaments resulting from a breakup of a longer filament, promoted by the controlled death or collapse of certain cells. Hormogonia exhibit gliding motility for several hours, are positively phototactic and lack heterocytes. Light is absorbed by thylakoids, photosynthetic membranes, which are arranged concentrically at the cell periphery, not stacked and not connected to the plasma membrane. They contain the chlorophylls *a* and *d*, in some cyanobacteria also chlorophyll *b*, as well as carotenoids and phycobilins as accessory pigments to capture light energy and convey it to the photosynthetic reaction centers located inside the thylakoid membranes. Phycobilins are blue or red water-soluble pigments and are present in large amounts. They are bound to proteins that form up hemispherical phycobilisomes which occur on the outer thylakoid surfaces. Several particles in the cytoplasm of cyanobacteria may represent storage products, that is, cyanophycin (a polymer of the nitrogen-rich amino acids asparagine and arginine), cyanophycan starch

(a polyglucan), and polyphosphate. In addition, lipid droplets, carboxysomes (polygonal aggregations of *Rubisco*, the key enzyme in CO₂ fixation), and gas vesicles may be present in the cytoplasm. Gas vesicles (assemblies of hollow, pointed cylinders, but not delimited by membranes) occur frequently in aquatic cyanobacteria and enable them for buoyancy and to confer vertical mobility in the water column. The cell wall of cyanobacteria is basically the same as for Gram-negative bacteria, that is, a thin peptidoglycan layer (a polymer composed of sugar derivatives and amino acids) is outside of the cell membrane (cytoplasm membrane). Outside of the peptidoglycan layer is a space surrounded by another membrane, termed outer membrane. A very characteristic feature of cyanobacteria is that they usually are surrounded by a mucilaginous sheath (extracellular polymeric substances [EPS], see entry “*Extracellular Polymeric Substances (EPS)*”), mostly composed of polysaccharides, which protects the cells from drying and enables them to attach to substrates.

Ecology

Cyanobacteria are widely distributed in aquatic and terrestrial environments, including such extreme habitats as hot springs, deserts, and polar regions (Whitton and Potts, 2000). Many cyanobacteria are diazotrophic, that is, they can fix atmospheric molecular nitrogen gas (N₂) into ammonia which is then further assimilated into amino acids and proteins. Nitrogen fixation is an inducible process and is exceptionally energy demanding. The environmental levels of ammonium or nitrate regulate it and it can only be performed if sufficient ATP (produced by photosynthesis) is available. The key enzyme of nitrogen fixation is nitrogenase, which is irreversibly inhibited by oxygen and, therefore, nitrogen can only be fixed under anaerobic conditions. Cyanobacteria that produce heterocytes are capable to fix nitrogen even in aerobic habitats, because several processes within the heterocytes (e.g., intracellular respiration) consume oxygen and the heterocytes’ thick cell walls reduce diffusion of oxygen into the cells. Cyanobacteria without heterocytes may fix nitrogen in the dark. Bloom-forming filamentous cyanobacteria devoid of heterocytes are responsible for fixing one-quarter of the total nitrogen in the oceans (Bergman and Carpenter, 1991). These cyanobacteria fix nitrogen in randomly distributed vegetative cells adjacent to each other within the filaments. Here and inside the colonies, the filaments may be depleted from oxygen. In addition, these species occur in tropical seas that are relatively low in dissolved oxygen. The ability to fix molecular nitrogen makes cyanobacteria attractive as symbionts for many eukaryotes because eukaryotes are not able to fix nitrogen. Very common occurrences of nitrogen-fixing cyanobacteria as extracellular symbionts are lichens, that is, symbioses with certain fungi (Friedl and Büdel, 2008, see entries “*Symbiosis*” and “*Fungi and Lichens*”). In the marine environment, cyanobacterial symbioses are known

Cyanobacteria, Figure 1 Different cyanobacterial morphotypes from pure culture. Figure a, d–g show strains recovered from tufa stromatolite biofilms of hardwater creeks: (a) coccoid unicellular *Synechococcus* sp. The cells adhere at each other to form at pairs representing the products of a recent cell division (Photograph taken by A. Hodačova); (b) *Myxosarcina* sp. Arp, printed with permission of the publisher). Scale bar, 20 μm .

with sponges, ascidians (sea squirts), and echiuroid worms in the benthos and diatoms, as well as dinoflagellates in the plankton. These symbioses can be significant in terms of the biogeochemistry of coastal and open-ocean areas (Carpenter, 2002). Planktonic diatom–cyanobacteria symbioses play a significant role in the ecology and biogeochemistry of the surface ocean (see entry *Algae, Eukaryotic*). Symbiotic associations with cyanobacteria are also known from plants. In the water fern *Azolla* and cycads where filamentous cyanobacteria with heterocytes occur within certain cavities inside the leaf and intercellular spaces inside the root, respectively (Lee, 2008; Graham et al., 2009). N_2 -fixing cyanobacteria are common in waterlogged rice fields and the importance of these naturally occurring prokaryotes in the nitrogen economy of rice cultivation has long been known (Whitton, 2000). To support the demand for nitrogen in rice cultivation, input of chemical N fertilizers is a prerequisite, but the inoculation with free-living N_2 -fixing cyanobacteria as biofertilizers has been shown to increase growth and crop yield of rice. An example for intracellular associations involving cyanobacteria can be found in certain diatoms (see entry *Diatoms*).

The cyanobacteria metabolic activities make quantitatively important contributions to the carbon, nitrogen, sulfur, and other biogeochemical cycles (Hayes et al., 2007). There is an enormous variety of habitats where cyanobacteria play important roles, but to discuss this comprehensively is beyond the scope of this article. Therefore, we confine the discussion of cyanobacteria ecology just to a few selected examples. Other examples may be equally intriguing and important. In the littoral zone of marine environments, cyanobacteria form thin adhering films on porous or soft granular rocks within the spray zone. Cyanobacteria of the littoral zone make a significant contribution to the productivity of rocky shores (Lee, 2008). In the open-ocean minute unicellular cyanobacteria (less than 2 μm in diameter) may occur in high concentrations due to their adaptation to low light and effective nutrient uptake kinetics. Here, cyanobacteria represent the major organisms of the picophytoplankton (Ferris and Palenik, 1998) that dominates biomass and production of these oligotrophic habitats. Massive development of nitrogen-fixing filamentous cyanobacteria occur in certain tropical waters and the large surface area produced by the cyanobacterial filaments forms miniature ecosystems (Carpenter et al., 1992; Lee, 2008). Also in freshwaters blooms of cyanobacteria are common. Bloom-forming cyanobacteria often release significant toxic substances, termed cyanotoxins, with physiologically two types, neurotoxins and hepatotoxins (e.g., Codd et al., 1999). Cyanotoxins may function as anti-herbivore chemicals and can inhibit the growth of other algae. Cyanobacteria are also well known from hot acidic springs throughout the world (e.g., Ward and Castenholz, 2000). Many physiological properties that make the cyanobacteria capable to adapt to a large variety of extreme and environmental conditions may also indicate

their long evolutionary history. Many cyanobacteria are able to tolerate low oxygen conditions and even free sulfide at levels much higher than those tolerated by most eukaryotic algae. Many terrestrial cyanobacteria can tolerate high UVB and -C radiations, which may also be reminiscent of an adaption to early earth's conditions. Some cyanobacteria can even confer anoxygenic photosynthesis where H_2S is utilized as an electron donor. Cyanobacteria are also very successful primary colonizers in terrestrial habitats due to their tolerance of desiccation and to water stress. In biological soil crusts of semideserts, for example, cyanobacteria play a key role in maintaining the stability of the surface (e.g., Büdel et al., 2009). As they bind sand and soil particles, cyanobacteria prevent erosion. They help to maintain moisture in the soil and contribute nitrogen to it through nitrogen fixation. That may even assist higher plant growth by supplying growth substances (Lee, 2008). The cyanobacterial genus *Arthrospira* (formerly *Spirulina*) is used as human food supplement; the *Spirulina* industry is of increasing economic importance. Large filamentous colonies of *Nostoc* are used in China as “hair vegetable” (Facai).

Many species of cyanobacteria have calcium carbonate in the enveloping mucilage of the cells; crystals of calcite may also be trapped in the mucilage excreted by the cells (see entry *Calcite Precipitation, Microbially Induced*). In the marine environment, trapping and binding of the sediments as well as carbonate precipitation by cyanobacteria led to the formation of stromatolites (see entries *Microbialites, Modern*, and *Microbialites, Stromatolites, and Thrombolites*). The production of laminae in the stromatolites depends on fluctuations ultimately derived from movements of the earth, sun, and moon, and requires rhythmicity such as daily photosynthetic cycle of the organisms in the stromatolites. Up to 2,000 million years ago, there were no grazers and boring organisms and, therefore, stromatolites grew uncontested. The occurrence and size of stromatolites declined dramatically after the evolution of grazing and boring organisms. Today stromatolites grow only in warm hypersaline waters inhospitable to grazers and borers (e.g., Shark Bay, Australia). Extant cyanobacteria do not calcify in open-ocean sea water because this water is normally not supersaturated sufficiently with calcium carbonate to allow calcification (Riding, 2000; see entry *Calcified Cyanobacteria*). However, even in extant freshwaters, calcification processes somehow similar to the stromatolite formation in marine environments occur, for example, in tufa-forming biofilms of karstwater streams (Arp et al., 2010). Epilithic cyanobacterial species may enhance calcium carbonate deposition, either by trapping particles or by contributing to communities where calcite and aragonite (in freshwaters) or other carbonates are precipitated. Endolithic species mainly occur in soft and porous limestone (Figure 1h) where they grow actively into the limestone at sites where removal of surface material occurs (Pentecost and Whitton,

2000; see entry *Endoliths*). Whether the cell surface polymers or the degradation of cyanobacterial sheath by bacterial metabolism promote the calcification is still unclear. The calcification seems to be a side effect of the cyanobacteria metabolism related to the alkalization of the surroundings during photosynthesis (Verrecchia et al., 1995). The living cyanobacteria try to limit the mineralization of the surface of their cells by some means. Nevertheless, when the calcification in cyanobacteria occurs, it is connected with their mucilaginous sheath. However, significant influence of cyanobacterial photosynthesis in the regulation of tufa-forming processes has been found recently (Bisset, 2008a, b; Shiraishi et al., 2008).

Fossil history and classification

Fossil evidence indicates that major lineages of cyanobacteria had originated 2.3–2.45 billion years ago (Eigenbrode and Freeman, 2006; Tomitani et al., 2006; Graham et al., 2009), well before the establishment of eukaryotes 1.5 billion years ago (Javaux et al., 2001). Even older fossils resembling cyanobacteria have been found in ancient stromatolites (e.g., Schopf, 2006) and geochemical evidence may also indicate an even earlier origin of cyanobacteria, but this is not left undisputed. Collectively, the available data suggest that oxygenic photosynthesis arose sometime between 3.4 and 2.3 billion years ago (Allan and Martin, 2007). For classification of the cyanobacteria, more recently a combination of phenotypic and genotypic characters has been used (Castenholz, 2001). The fact that cyanobacteria have an algal way of life – cyanobacteria “usually behave like algae” (Wilmotte, 1994) – led to treat them as plants under the botanical code of nomenclature until the late 1970s (e.g., Anagnostidis and Komárek, 1985). However, as cyanobacteria are essentially prokaryotes, their treatment under the bacteriological code of nomenclature seems more appropriate (e.g., Castenholz, 2001). For a review of the difficulties of cyanobacteria classification, see Hayes et al. (2007). Based on the most recent broad-based description of cyanobacterial taxonomy (Castenholz, 2001), cyanobacteria are classified into five subsections (Subsections I–V) which correspond to the five orders Chroococcales, Pleurocapsales, Oscillatoriales, Nostocales, and Stigonematales which have been erected under the botanical code of nomenclature. Some of the groups described by this current classification scheme are known to be polyphyletic in molecular phylogenies (for reviews see, e.g., Hayes et al., 2007). This shows that taxonomy of cyanobacteria is still in a state of flux. Still more work using multiple gene analyses as well as correction of misidentified strains in DNA sequence databases and culture collections is required to achieve progress toward a more robust taxonomy of the cyanobacteria.

Summary

Cyanobacteria form a large and morphological diverse group of photoautotrophic Gram-negative bacteria. Many cyanobacteria have large cells like the eukaryotic algae with which they share oxygenic photosynthesis. Cyanobacteria occur in a broad variety of forms, from solitary unicells over colony forming and undifferentiated filamentous types to more complex forms that even display the hallmarks of multicellularity. There is strong evidence that cyanobacteria are the oldest microorganisms performing oxygenic photosynthesis, dating back to about 2.45 billion years. Cyanobacteria exhibit a broad environmental tolerance range, which makes them well adapted to live under extreme and fluctuating conditions. From an evolutionary point of view, it appears that cyanobacteria may have been forced by the “modern” eukaryotes to withdraw themselves into such habitats. Modern cyanobacteria are recognized for their ability to occupy diverse aquatic and terrestrial habitats, cyanobacteria produce organic compounds used by other organisms, and they stabilize sediments and soils. Many cyanobacteria can fix atmospheric molecular nitrogen gas (N₂) into ammonia which is then further assimilated into amino acids and proteins. Nitrogen-fixing cyanobacteria increase soil and water fertility and are particularly attractive as symbionts, for example, to form lichens with fungi or being endosymbionts in plants, some metazoa, dinoflagellates and diatoms. The cyanobacteria metabolic activities make quantitatively important contributions to the carbon, nitrogen, sulfur, and other biogeochemical cycles.

THROMBOLITES

Thrombolites (Greek: *thrombos*, clot; *lithos*, stone) are “cryptalgal structures related to stromatolites, but lacking lamination and characterized by a macroscopic clotted fabric” (Aitken, 1967, p. 1164).

Wadden Sea: name of the world’s largest tidal flat system in Central Europe

Definition

Tidal Flat. A wide and almost flat coastal area between the mean upper and lower tidal seawater levels (eulitoral) exposed to the rhythmic tidal water movements. It consists of unconsolidated sediments and is bordered toward the land by permanently emerged areas and toward the sea by the permanently submerged sublittoral zone.

Introduction

Tidal flats occur worldwide in shallow coastal regions: in the tropics, subtropics, temperate zones, and subpolar, and polar regions. In the tropics and subtropics, such as at various regions of the east coast of South America, in Africa, Bangladesh, Indonesia, and Australia, tidal flats are closely associated with mangrove ecosystems. In other places, such as Mauretania, the Persian Gulf, and the coast of Texas, USA, tidal flats are either wide and open coastal stretches or protected by barrier islands. Large tidal flat

areas adjacent to marshlands exist on the Atlantic coast of the USA (North/South Carolina, Georgia) and Canada (Nova Scotia, Bay of Fundy), Korea, and in Europe along the Atlantic coast (Portugal, Spain, France, and Great Britain), and the North Sea. At the southern coast of the North Sea, the worldwide largest tidal flat system, the Wadden Sea ranges from The Netherlands (den Helder) through Germany to Denmark (Esbjerg). Subpolar and polar tidal flat systems are found in southern Chile, Alaska, and Siberia. Tidal flats may also develop in shallow estuaries, and thus their sediments may partially exhibit riverine properties.

A special type of tidal flats is wind-induced; these wind flats form along shallow coastlines with very little tidal water movements but occasionally persistently strong winds. The winds lead to the emergence or submergence of shallow areas for irregular periods, and the flats are characterized by microbial mats and sediments similar to those of regular tidal flats.

Formation and shaping forces

Along shallow coastlines with little wave action, the rhythmic incoming and outgoing tidal currents are the main driving forces for establishing and structuring tidal flats. A critical tidal range of at least 1 m is a prerequisite for the formation of a tidal flat. The incoming tide imports dissolved nutrients and particulate inorganic and organic matter, which settle out during reduced water movement at slack tide. This hydrographic energy gradient leads to a fractionation of the suspended material according to its settling properties. The finest material, the mud fraction (>50% of the material with a particle size <63 µm and the highest content of organic carbon up to 10% of dry weight) settles at the lowest current velocity and thus in the shallowest and least energetic zones. The other fractions consist of sandy (<5% mud) and mixed sediments (5–50% mud) and form the bulk of the sediment in highly and intermediate energetic areas (Chang et al., 2006). As a consequence, material and nutrients accumulate in tidal flats and provide the basis for highly productive ecosystems (Postma, 1981). Additional input of particulate organic and inorganic matter and nutrients may come from the adjacent coastal areas permanently emerged and/or by pore water (Kasten, this volume) and groundwater via tidal pumping (only inorganic nutrients and dissolved organic matter). Export of matter occurs mainly in the dissolved form and net export of particulates occurs only when re-suspension exceeds sedimentation for more than a tidal cycle, during storm events. The interplay of coastal and tidal currents, settling, re-suspension, and fractionation of suspended matter and sediment, results in the formation of typical depositional features, such as banks, islands, barrier island systems with distinct sediment structures, and drainage channels of different sizes and depths (Figure 1). Because of the ample nutrient supply, tidal flats are hot spots of marine productivity and biodiversity.

GEOCHRONOLOGY

Volker Liebetrau
Leibniz Institute of Marine Sciences, IFM-GEOMAR,
Kiel, Germany

Synonyms

Age determination; Dating

Definition

Geochronology. Determination of ages and time intervals for geologic materials and processes on geologic, archeologic, and historic time scales. The science of investigating and reflecting the chronology of the earth constituents as induced from geologic data, based on absolute and relative dating methods.

Age, absolute. Age determination based on radioactive elements, their rates of decay and physical measurements, resulting in an actual age given in years for the analyzed geologic material (e.g., mineral, rock, fossil, fluid).

Age, relative. Age information based on stratigraphic anomalies (e.g., lithostratigraphic and biostratigraphic principles, field observations) or utilizing chemical reaction rates (e.g., diffusion, exchange, oxidation, hydration) as a measure of time.

Units. Geochronologic data are presented as yr BP (years before present), as ka (age date in thousands of years), as kyr (time interval in thousands of years, e.g., between distinct age data), following the same principle as Ma and Myr (millions of years), respectively. Alternatively, the mathematical expression in years, times order of magnitude is used and favored for age data and time intervals in the range of billions of years and the description of half-lives (e.g., 4.47×10^9 years, half-life of the ^{238}U isotope).

Introduction

The term “geochronology” may reasonably be used in reference to all principles and methods employed in geology to determine the relative and numerical ages of all kinds of rocks (Walsh, 2001). The immense age of the Earth and the long-term duration of processes changing the morphology and composition of the Earth’s crust and interior were progressively recognized throughout the last centuries. Geoscientists developed and established a relative chronological systematic based on lithostratigraphic and biostratigraphic principles, including global correlations and ongoing refinement. The actual state of the art is presented by the International Commission on Stratigraphy (ICS, 2009; <http://www.stratigraphy.org/upload/ISChart2009.pdf>).

In contrast, the direct determination of absolute ages required fundamental new physical approaches and analytical methods in the field of geochemistry. The basis for “geochronology” as a new geoscientific discipline was provided by the early description of radioactive transformations more than 100 years ago (Rutherford, 1906). An actual status in combining detailed knowledge of relative age successions with precise absolute ages and the impact of resulting chronostratigraphy on the understanding of the Earth’s geologic evolution is presented in concise manner by Ogg et al. (2008). A still valid and systematic overview about the broad variety, principles, scopes, potentials, and limitations of physical and chemical dating methods is given in a comprehensive way by Geyh and Schleicher (1990). This work is especially

useful for non-geochronologists on search for analytical methods most suitable for their specific demand in geologic time series data, providing fundamental knowledge for collaborative approaches.

Geochronology in geobiology

The science of geochronology provides the fourth dimension of geological and geobiological processes as a crucial requirement for their reconstruction in space and time, e.g., the determination of changes in biochemical fluxes, habitat conditions, and their comparison through Earth's geological and biological evolution.

Due to the fast developing field of geobiology, the increase in recognition and understanding of biological mediated formation and destruction of minerals, stones, and rock sequences the demand for high resolution, and absolute age data is continuously evolving.

In the following some essential, very different, and often in geobiologic approaches preferred concepts of age determination are explained.

Some essential concepts

Counting of structural and chemical anomalies

(High resolution, high precision, robust, low analytical effort, short time scales, strict prerequisites on growth systematic for high reliability):

Well known is the counting of growth, sedimentation, and precipitation cycles in correlation to short time intervals of orbital cycles in a broad variety of archives. Typical examples are changes of tree-ring structures (season-depending density, dendrochronology), layering of varves in sediments (seasonal change in detrital and organic input), sclerochronology of corals (annual growth bands), chemical lamination within sclerosponges, and fast growing Fe-Mn precipitates (reflecting seasonal changes in temperature and oxygenation, respectively).

Assuming the youngest part of a succession as recent reference point, this concept allows very precise and reliable age data, as long as continuous growth is ensured and no hiatus is observed. The latter would interrupt and extend the age record to unknown length, until independent radiometric age data provide new reference points. Alternatively, the identification of characteristic markers for over-regional to global events allows the combination of such archives from different locations and their sequential connection to longer time series (e.g., regionally resolved reconstruction of the Little Ice Age; Mann, 2001).

Radiometric age determination/radiochemistry

(Precise absolute ages, independent from growth structure and stratigraphy, decadal to billions of years time scales, robustness, and uncertainties depending on method and age, high analytical effort, on highest level of precision often depending on physico-chemical models, and correction assumptions):

Radiochemistry and related methods for radiometric age determination are the most powerful tools in geochronology, providing independent absolute ages for samples throughout the Earth's evolution. Their principles are based on changes of the isotopic composition of an element in the sample, due to the decrease of radioactive parent isotopes by decay and/or the increase of radiogenic isotopes as product of decay. Both processes are depending on isotope-specific half-lives, therefore, providing directly chronologic information. Radiometric methods belong to the broad field of Isotope Geochemistry. Detailed information about isotope systematic, analytical procedures, data interpretation, and geologic and geochemical background is presented by Dickin (2005), Faure and Mensing (2005), and Allègre (2008).

Two major geochronological principles, **deficiency** and **in-growth**, are dominating these methods and are explained in examples given below. In general, the deficiency principle can be described as determining the age by calculating the time required for the decay of a radioactive isotope from an assumed starting concentration or ratio down to the actually measured value. The starting value is equivalent to an excess concentration of a radioactive isotope above its equilibrium activity within its decay chain. The initial degree of excess depends on the investigated environment and the isotope system of interest. Required assumptions on the initial values are generally based on the measurements of recent analogues. Deduced ages are often presented by adding "excess" or the abbreviation (exc.) to the related isotope for method identification, especially if this isotope or isotope ratio is relevant for different geochronological methods.

In contrast, if a sample is strongly depleted in a decay product down to negligible or well-known initial concentration, e.g., by element fractionation during sample growth or crystallization, the in-growth principle can be used for direct age determination.

The activity ratio between decay product and parent isotope is increasing with time until equilibrium is reached. The time span required to reach the actually measured concentration or ratio is directly related to the half-life.

The maximum limit of age determination is reached for both principles in samples reflecting equilibrium activity within the analytical uncertainty, just reached from different directions (decay/in-growth). As a rule of thumb, for the robust estimation of the dynamic range of a geochronological approach, a factor of 4–8 (depending on the analytical technique and its precision) could be applied on the half-life of the relevant isotope. Best control on age reliability and accuracy is given where both principles could be applied on the absolute determination of a sample age or duration of a process.

It should be considered that radiometric methods can be easily overestimated and misinterpreted due to manifold requirements in sample quality, preparation, and analytical

effort. As more precise modern analytical techniques allow the determination of isotope ratios and concentrations, more attention should be given to the clear distinction between precision of a measurement and the accuracy of the deduced age. Especially in terms of realistic age uncertainties, the range of whole procedure blanks, reproducibility, and applied correction factors must be well known.

A general requirement of radiometric dating methods is a closed-system behavior of the sample material after formation until preparation for measurement. Differential analyses combining **relative age** successions with subsequent absolute age determinations are fundamental to achieve the highest level of accuracy, as, e.g., required for international chronostratigraphic calibration approaches. Relative age determination is generally based on the field and the microscopic observation and biostratigraphic classification. Absolute age determination is most reliable if independent measurements could be applied. In any case, the expensive isotope analyses should be combined with mineralogical and/or chemical pre-investigations for verification or estimation of potential secondary perturbations. Main issues are mineral composition and purity, the detection of secondary recrystallization processes, and chemical exchange reactions. For robust results of isotope approaches, a useful guiding principle includes to (1) look carefully, then to (2) select well-documented samples, before (3) crushing and homogenizing these materials for lab procedures.

Radiometric example A: cosmogenic ^{14}C /radiocarbon method/deficiency principle

Substrates for geochronological approaches in geobiology often consist of carbonic components, therefore the radiocarbon method, based on the cosmogenic nuclide ^{14}C , is especially advantageous and often suitable. ^{14}C is the least abundant of the three natural carbon isotopes (^{12}C , 98.98%; ^{13}C , 1.11%; ^{14}C , 1.176×10^{-12} atoms per ^{12}C atom) and decays with a half-life of 5,730 years. Due to its general dependence on cosmic activity and processes, it belongs to a group of cosmogenic and geochronologic relevant nuclides like ^{10}Be (Beryllium), ^{36}Cl (Chlorine), and ^{129}I (Iodine) of very different chemical affinity and dating potential.

^{14}C is mainly produced by the collision of low-energy cosmic ray neutrons with nitrogen atoms (^{14}N) in the upper atmosphere, rapidly oxidized to CO_2 and available for metabolic processes and mineral precipitation. A complex system of various exchange processes between the atmosphere, the biosphere, and the hydrosphere results in a kind of dynamic equilibrium resulting in rather constant $^{14}\text{C}/^{12}\text{C}$ ratios.

As soon as organic matter (e.g., by death of an organism) or a mineral (e.g., by biomineralization) is excluded from equilibration processes with the ambient carbon, the carbon isotopic composition changes systematically

by decay of ^{14}C . The decreasing ^{14}C concentration is ideally transferable to direct age information, i.e., about the date since the system was closed.

The rather short half-life of ^{14}C limits this method in general to samples younger than 50 ka. Extremely challenging is the application on samples of heterogeneous carbon supply, like marine cold seep and AOM (anaerobic oxidation of methane)-related carbonates, which tend to be influenced by varying proportions of buried methane-driven ^{14}C from older sources. Due to the low abundance, precise, and high resolution, ^{14}C measurements on small samples or growth increments (e.g., 0.002 g of a coral fragment) are restricted on very expensive and rare accelerator mass spectrometry (AMS) facilities. High-resolution analyses and chronological profiles are restricted to mechanical preparation methods using handheld mini- and computer-controlled micro-drilling devices.

Radiometric example B: Uranium decay series/ $^{230}\text{Th}/^{234}\text{U}$ /in-growth principle

The U decay series offers a wide range of established geochronological methods, suitable from marine mineral precipitation processes of the last decade ($^{230}\text{Th}/^{234}\text{U}$) back to the oldest rocks and minerals ($^{238}\text{U}/^{206}\text{Pb}$) on Earth, billions of years in age. Bourdon et al. (2003) presented an outstanding selection of papers covering the broad scope of Uranium series geochemistry.

Considering geobiological approaches, the affinity of many organisms to build directly calcium carbonate skeletons and indirectly remnants of biologically mediated precipitation processes (chemohierms) favors the formation of high-resolution archives, enriched in U and poor in Thorium.

An important and often applied approach for carbonate samples of the last 350 kyr is the in-growth of ^{230}Th (half-life of 7.5×10^4 years) by the decay of primary incorporated ^{234}U (half-life of 2.45×10^5 years). The change of their isotopic ratio with time during closed-system conditions provides direct geochronologic information. In regard to precision, reliability, and robustness it is crucial to select and prepare pristine sample parts without secondary overprint and with lowest ^{232}Th -content. The latter reflects the degree of initial Th incorporation which controls the influence of correction factors for initial element and isotope ratios on the final age calculation.

The state-of-the-art analytical procedure is based on multicollector – inductively coupled plasma – mass spectrometry (MC-ICP-MS) combined with low-blank clean-lab preparation procedures. A direct comparison of sclerochronology and U-series analyses on smallest sample amounts of a continuous drill core from a tropical reef demonstrated the analytical potential of extending this technique to multi-static multiple ion counting (MIC)-ICP-MS (Fietzke et al., 2005). Another promising step toward high-resolution U-Th age data was presented by Potter et al. (2005) who used laser-ablation-MC-

ICP-MS. Unfortunately, this in situ approach is still hampered by the high uncertainties of low-counting statistics on samples younger than 10 ka. Meanwhile, recent efforts in conventional data precision and sample selection pushed the maximum limit of age determination with the U-Th method to the successful dating of extraordinarily well preserved 600-ka-old corals (Andersen et al., 2008).

Summary

Geochronology in geobiologic approaches offers detailed insights into the time scales of biological processes, changes in biochemical fluxes, and the identification of driving mechanisms. Still open challenges are the rather low sample throughput of conventional clean-lab preparation procedures, the necessary achievements in precision for in situ approaches, and the methodical extension toward reliable dating tools covering the last millions of years.

Definition

Geomycology. The scientific study of the roles of fungi in processes of fundamental importance to geology

Introduction

Fungi are chemoorganotrophic (heterotrophic) organisms relying on organic carbon sources for energy and metabolism, and ubiquitous in aquatic and terrestrial environments. They are important as decomposers, animal and plant mutualistic symbionts and pathogens, and spoilage organisms of natural and manufactured materials (Gadd, 1993a, 1999, 2006; Burford et al., 2003a). They also have a role in the maintenance of soil structure due to their predominantly filamentous branching growth habit (each filament is called a hypha; plural = hyphae; all the hyphae constitute the mycelium) and frequent exopolymer production. Fungi have important roles in the biogeochemical cycling of the elements (e.g., C, N, P, S, metals), and this is linked with their ability to adopt a variety of growth, metabolic, and morphological strategies, their adaptive capabilities to environmental extremes and, their mutualistic associations with animals, plants, algae, and cyanobacteria (Gadd and Griffiths, 1980; Burford et al., 2003a; Gadd, 2004a, 2007a, b; Braissant et al., 2004; Gadd et al., 1984, 2005; Fomina et al., 2005a, 2006a, b) (Table 1). Fungal polymorphism and reproduction by huge numbers of spores underpins successful colonization of many different environments. Most fungi exhibit a filamentous growth habit which enables explorative or exploitative growth strategies, and many form linear organs of aggregated hyphae for protected translocation of nutrients (Jacobs et al., 2002, 2004; Boswell et al., 2002, 2003, 2006; Fomina et al., 2005a, b). Some fungi are polymorphic, occurring as both filamentous mycelium and unicellular yeasts or yeast-like cells, as in the black microcolonial fungi colonizing rocks (Gadd and Griffiths, 1980; Sterflinger, 2000; Gorbushina et al., 2002a, b, 2003). Some fungi are predominantly unicellular such as the yeasts, exemplified by *Saccharomyces cerevisiae*.

A broad appreciation of fungi as agents of biogeochemical change is lacking within geobiology, and apart from obvious connections with the carbon cycle, they are frequently neglected within broader geomicrobiological and geochemical contexts. While the geochemical activities

SPECIES (MICROBIAL)

Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization; thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy. See entry “*Microbial Communities, Structure, and Function*” for further reading.

SPELEOTHEMS

Roman Aubrecht
 Comenius University, Bratislava, Slovakia

Synonyms

Cave deposits; Cave sinters

Definition

The word “speleothem” is from Greek and means “cave deposit.” According to its origin, this term can be used for any cave deposits, but it is used mostly for secondary mineral deposits formed (precipitated) in caves. In this entry, speleothem is understood as constructively formed, new cave material. Materials originated by destructive phenomena, such as erosion, weathering, etching, biocorrosion, or bioerosion are not subjects of this entry.

Biogenic and abiogenic speleothems

Most of the speleothems originate inorganically by precipitation of various minerals from solutions. The minerals are dissolved by undersaturated fluids and precipitate when the solutions become supersaturated, e.g., by evaporation, outgassing, or pH changes. Mineralogical compositions of speleothems vary depending on the environment in which the caves are formed. The most common speleothem-forming mineral is calcite (as most of the caves are formed of limestones), forming well-known sinter forms, such as dripstones (stalactites, stalagmites) and flowstones. Locally, mostly in hydrothermally influenced cavern systems, speleothems may be formed by its rhombic modification – aragonite. Gypsum and other sulfate minerals commonly form speleothems in gypsum karst but are widespread also in other types of caves. Speleothems formed in silicate rocks (e.g., sandstones, quartzites, granites, etc., [Figure 1](#)) are relatively rare, composed mostly of various forms of silica (from opal-A to microquartz depending on its recrystallization). Other speleothems can be represented by ferroan and manganese oxides and hydroxides forming cave flowstones.

Speleothems, Figure 1 Examples of microbial speleothems – cave stromatolites encrusted by silica in the sandstone cave Cueva Charles Brewer, Chimantá Plateau, Venezuela. (a–c) Mushroom-like stromatolites growing on the cave walls. (d) Slabs of stalactitic and mushroom-like stromatolites. Columnal stromatolites (*dark*) are formed by filamentous microbes; *white*, chalk-like parts represent stromatolites formed by tiny spherical microbial colonies. (e) Other shape of stromatolites with prevailing laminae formed by filamentous microbes.

Overall inventory of cave minerals is very large (for a summary see Hill and Forti, 1986).

The formation of some speleothems is influenced by organisms. The organisms can be passively covered (encrusted) by speleothems or they can directly biologically mediate their formation. In some cases it is not easy to distinguish between the active and passive role of the organisms. Biological mediation of mineral precipitation usually involves biomineralization (biomineralization (general aspects); microbial biomineralization; silica biomineralization (sponges)) and/or organomineralization. Biomineralization means direct precipitation of mineral skeleton (either internal or external) or encrustation by the organism itself (*syn vivo*). Organomineralization in

which the precipitation of minerals is mediated by organic matters produced by the organisms and by changing the ambient conditions (e.g., pH, enrichment or depletion of the solution by metabolism, etc.). They can occur either *syn vivo* (when the organisms are alive – they influence the ambient environment actively) or *postmortem* (after the organisms are dead – the ambient environment is influenced by the decay products of the organisms).

Organisms which mediate speleothem formation

The speleothem-forming organisms are mostly microorganisms (Archaea, Bacteria including Cyanobacteria, and Algae); more evolved multicellular organisms are

mostly represented by Fungi, mosses and lichens. Also roots of higher plants, penetrating to caves can form speleothems. All the mentioned organisms form speleothems from the autochthonous cave material (mostly taken from solutions). Excrements of animals (e.g., bats) can turn to well-known cave deposit – guano. Unlike the previously mentioned speleothems, guano and its minerals (rich group of phosphates, nitrates, and organic minerals) are completely allochthonous in caves, introduced originally from outside.

Microbes

Microbes inhabiting caves are mostly chemolithoautotrophic or chemoheterotrophic, i.e., their nutrition is not dependent on sunlight (for review see Konhauser, 2007). The exception is the so-called lampenflora, represented by phototrophic cyanobacteria and other algae which live on the lightened places in show caves. Phototrophic microorganisms normally inhabit the entrance areas and the number of microorganisms declines rapidly toward the twilight areas. Unicellular algae – diatoms – were found to contribute to the formation of speleothems, which occurred close to the entrance (Kashima et al., 1987; Kashima and Ogawa, 1995). Some cyanobacteria, although originally phototrophic, can adapt themselves to darkness and change their life mode to heterotrophic. For instance, the genera *Fisherella* and *Calothrix* were found to be able to change their mode of life to slow heterotrophic in complete darkness (Whitton, 1987). Some cyanobacteria were found to inhabit dark cave environment e.g., *Geitleria calcarea* and *Scytonema julianum* (Friedman, 1955; Bourrelly and Depuy, 1973) and contribute to speleothem formation. *Nostoc* is also easily adaptable to a heterotrophic mode of life, and is a common symbiont (endobiont) in lichens and higher plants. In addition to photosynthesis, *Nostoc* is able to perform nitrogen fixation (symbiosis of higher plants with *Nostoc* provides them with nitrate). *Nostoc* has also been reported from caves in Israel, growing in various zones, from well illuminated to complete darkness (Vinogradova et al., 1998). Moreover, *Nostoc* is also supposed to form large opal stromatolites in the Venezuelan sandstone caves (Figure 1; Aubrecht et al., 2008).

The most common in cave environments are chemolithoautotrophic and chemoheterotrophic microorganisms. Similar to other microorganisms, they use CO₂ as their carbon source but their source of energy comes from different chemical reactions. Chemoheterotrophs utilize preformed organic compounds, whereas chemolithoautotrophs utilize mostly inorganic compounds (Konhauser, 2007). These organisms and processes they utilize are numerous but only some of them are important speleothem-forming factors. Sulfur-oxidizing bacteria, such as *Beggiatoa* or *Thiothrix*, are responsible for deposition of elemental sulfur and sulfates in caves. They are particularly important in the caves with sulfur-rich waters, e.g., Parker Cave, Kentucky (Barton

et al., 2001). Bacteria also mediate formation of iron oxide and manganese oxide flowstones (Gradziński et al., 1995). Finally, they may also mediate formation of the carbonate speleothems, which are the most widespread speleothems in the world (Taboroši, 2006).

Fungi

Fungi are ubiquitous in all caves, being mostly chemoheterotrophs. They not only inhabit the caves but they actively contribute to the formation of some carbonate speleothems, such as a particular, soft form of sinter – moonmilk (Gradziński and Szulc, 1997; Gradziński et al., 1997).

Mosses

Mosses (often together with lichens) occur mostly in the near-entrance areas and are mostly passively encrusted by minerals (mostly calcite), thus forming moss tufas (Taboroši, 2006).

Plant roots

In shallow-placed galleries, plant roots sometimes penetrate from the surface. They are often mineralized, forming the so called rootsicles (Taboroši, 2006). It is not yet known whether they represent passive encrustations, or the roots actively mediate the precipitation. This is also true for other plant (and animal) remnants which are locally transported to the caves from the surface.

Marine organisms forming speleothems

Marine organisms represent a special chapter in the genesis of organic-mediated speleothems. Marine water, bringing nutrition to submarine caves, enables many organisms to live in this cryptic environment. Sessile organisms overgrowing the cave walls easily turn into speleothems. Very common are cryptic stromatolites (Reitner, 1993) formed by nonphotosynthetic organisms or serpulid buildups (Taboroši, 2006; Schlögl et al., 2008) formed by these filter feeders in submarine caves.

Methods of recognition of the speleothem-forming microorganisms

Cave-dwelling microorganisms, including those which contribute to speleothem formation, are considered to be extremophiles. That means they are organisms living in and adapted to environments which are not prolific for many organisms and which lack many aspects necessary for life; in caves, it is mainly the lack of sunlight and generally oligotrophic character of the environment. Adaptation of these organisms to the cave environment makes them uneasy to be determined by classical microbiological methods (Barton, 2006). For instance, for the complete identification of cyanobacteria, about 37 characteristics are needed, e.g., cell morphology, ultrastructure, morphology of colonies or filaments, genetic characteristics (DNA), cultivation conditions, and life conditions (Castenholz, 2001). Cultivation was so far the most

important tool in microbiology. This tool was developed mostly for medical purposes and was optimized for the research of microbes inhabiting animal bodies. However, only a small portion of free-living microbes is cultivable from environmental samples, including caves. Therefore, new culture-independent *in situ* methods have been developed for the detection of microbial groups in natural microbial assemblages, based on the molecular analysis of their DNA (Barton, 2006). Among these methods, one of the most important is *in situ* hybridization (FISH). Biomarker analysis may also be a suitable tool for the analysis of speleothems, in which only organic matter remained after dead, decayed organisms.

Conclusion

Speleothems are secondary mineral deposits formed in caves. They can form either inorganically or originate biologically. The inorganic formation pathway is based on physical precipitation from solutions after they become supersaturated. Biologically mediated precipitation is influenced by organic matter produced either by living or dead organisms and does not necessarily involve supersaturated solutions. This kind of precipitation acts via biomineralization or organomineralization, and may result in various sorts of minerals, such as calcite, elementary sulfur, sulfates, iron and manganese oxides, etc. The main biological protagonists forming speleothems are microbes. They are mostly chemolithoautotrophic and chemoheterotrophic microorganisms, or phototrophic organisms that changed their life modes and adapted themselves to the cave environment. Normally, the phototrophs are active only in near-entrance parts of caves. Other organisms forming speleothems are mosses, lichens, higher plants, or animals. These are however, mostly passively encrusted by minerals; their potential for active biological mediation to form speleothems is still the matter of research.

Sponge-associated bacteria; Sponge-associated microbes; Sponge-associated microbiota; Sponge bacteria; Sponge-microbe systems; Sponge symbionts

Definition

Sponges are sessile multicellular aquatic animals (Lat. Porifera = bearing pores) whose bodies have a typical body plan which allows water to pass through the animals. Sponges are characterized by a skeleton made of calcareous, siliceous spicules or horny fibers.

Sponge microbes: Bacteria and archaea that live in close and permanent association with sponges, usually in the mesohyl between sponge cells.

Introduction

Sponges are sedentary benthic organisms found in shallow waters on tropical coral reefs to the Arctic and the deep sea. Some species, however, are restricted to freshwater ecosystems. Sponges are characterized by a typical body plan built around a system of water canals and chambers (Figure 1a). Within the chambers, flagellated cells called choanocytes produce a water current that enters the sponge body through surface pores (ostia) and leaves through larger openings called oscula. Hence, sponges are filter feeders and incorporate particles from the water as energy and nutrient source. An external cell layer (pinacoderm) encloses the sponge mesohyl, a glycosidic matrix containing several cell types which perform a variety of functions. Sponge cells show a low degree of specialization and a high degree of independence so that the sponge body in some respect resembles a protozoan colony. However, sponges are, without any doubt, placed as true members of the Metazoan (Ax, 1995; Müller, 1998a, b).

Sponges have been grouped into three classes: Calcarea, Hexactinellida, and Demospongiae. Calcarea are characterized by the presence of calcareous spicules. The upgrade of this class to the phylum level has recently been proposed by Borchiellini et al. (2001). Hexactinellida are characterized by siliceous spicules of hexactine structure and syncytial tissue organization.

Demospongiae, the most numerous and diverse class, is a nonmonophyletic group (Boury-Esnault, 2006). They generally have a mineral skeleton made of siliceous spicules, but several lineages, like the common bath sponge, have no mineral skeleton but a network of fibers instead. Modern sponge phylogeny is now based on a combination of molecular methods and sponge morphological features, but sponge spicules are still important features for species determination and identification of sponges in the fossil record.

Sponges form one of the deepest radiations of the Metazoa and can be regarded as one of the oldest animal phylum still alive. The spicule record for sponges starts in the late Proterozoic (Reitner and Wörheide, 2002), while chemofossil records even indicate the presence of sponges – or their direct ancestors – already in the early Proterozoic: specific C₃₀ steranes (24-isopropylcholestanes), which are unambiguous biomarkers for demosponges, were found in 1,800 Ma old stromatolites (McCaffrey et al., 1994; Moldowan et al., 1994).

Choanoflagellates, a monophyletic group of protists which can show a colonial lifestyle, are the closest sister group of the Metazoa (Medina et al., 2001) and show a morphological resemblance to the flagellated choanocytes of sponges. It is, therefore, widely agreed that the “urmetazoa,” the last common ancestors of all Metazoa, would have many traits found in sponges (see review in Gaidos et al., 2007).

Numerous sponge species host vast amounts of microbes in their mesohyl matrix (Figure 1b and c) or sometimes in specialized cells, while others contain only few or no microorganisms at all. The former have been termed bacteriosponges (Reiswig, 1981) or high-microbial-abundance sponges (Hentschel et al., 2003) while the latter are referred to as “low-microbial-abundance sponges.” Bacterial population densities in bacteriosponges may reach 10⁸–10¹⁰ microbes per gram of sponge wet weight, while those in low-microbial-abundance sponges are within the range of natural seawater.

The first studies exploring the microbial community of sponges were based on electron microscopy and isolation of microbes and yielded invaluable information about the microorganism morphotypes and their specific location within the sponge (e.g., Wilkinson, 1978). Microbes were found to exist extra- and intra-cellularly (e.g., Vacelet and Donadey, 1977) and even inside the nucleus of sponge cells (Vacelet, 1970). More recently, the advent of molecular techniques have enabled a detailed phylogenetic description of the microorganisms associated with sponges (Hentschel et al., 2006), whereas environmental genomics have given insights into their metabolic and physiological properties (Grozdanov and Hentschel, 2007).

Phylogenetically complex, yet highly sponge-specific microbial communities were identified in numerous species over large geographical ranges (Hentschel et al., 2002). Sequences representing 16 bacterial phyla and both major archaeal lineages have been recovered to date (see

Definition

Salt: chloride, sulfate, phosphate, carbonate, bicarbonate salts of primarily sodium, magnesium, calcium, and potassium.

Lake: an enclosed body with or without water entering it from a stream, rain, or snow melt.

Ephemeral lake: a lake formed only following rain or snow melt, which dries up during the rest of the year.

Thalassohaline: salts in a lake derived from the evaporation of seawater with the dominant ions of sodium and chloride as found in the ocean.

Athalassohaline: salts in a lake derived from rocks and geological weathering and dominated by magnesium, calcium, and sulfate.

Alkaliphilic lake: also called soda lake. A lake in which the dominant ions are sodium and bicarbonate and carbonate. This causes the lake to have an alkaline pH.

General description of saline lakes

Saline lakes are a natural worldwide phenomenon. They can be found on all continents and in most countries, and they are frequently recognizable by their name – for example, Salt Lick, Salt Lake, Salt Pond, and Salt Marsh. They range in salinity from just above the salt content of sea water (>3.2% salts) to hypersaline lakes (>20% and up to saturation with respect to salts). Examples of saline lakes include, at the lower end, salt lakes in Antarctica, the Caspian Sea, which borders five countries and has

a salinity slightly less than that of seawater, and the Salton Sea in California. At the upper end in salt concentrations are the Dead Sea bordering Israel and Jordan, the soda lakes of North Africa, and Quinghai Lake in China. A general characteristic of saline lakes is that they are terminal lakes, which means that although rivers may flow into them, they have no significant outflow. Therefore, as the water evaporates, the lakes become more salty and in some cases may dry up completely forming salt basins or playas especially in extremely arid environments. In Australia, for example, occasional rains may cause the dry salt basins to become lakes, and these then are called ephemeral salt lakes.

Saline lakes are typically divided into two main types: athalassohaline and thalassohaline. The former refers to lakes which have a different chemical ratio of the main cations from what is found in seawater, while the latter refers to lakes with the cation ratio similar to seawater. [Table 1](#) lists the sodium + potassium ion to calcium + magnesium ion ratios and summarizes the chemical composition of a variety of saline lakes thus showing the wide range of lake types possible.

The data in [Table 1](#) indicate that a subset of the athalassohaline lakes exists. These lakes have a high concentration of carbonate and therefore a high pH. These are the soda lakes or alkaline lakes. They, too, are found worldwide and are described below. No Antarctic lakes are listed in [Table 1](#) because the surface waters are generally only very slightly saline (less than seawater) and it is only with depth, often greater than 10 m, that true saline waters are found. In general, it is the bottom waters that are hypersaline with little turnover to bring the saline waters to the surface. The chemical compositions of Antarctic lakes have been reviewed by Matsubaya et al. (1979).

The reason for the differences in the chemical composition lies in the origins of the various types of lakes. The thalassohaline lakes were generally formed during the

Pleistocene period (Hammer, 1986) and are the result of seawater intrusion before tectonic activity created the mountains which cut the bodies of seawater off from the ocean. Brine springs are formed from the dissolution of salts deposited during evaporation of the seawater. As surface water seeps into the ground, the water percolates downward and eventually encounters the salt, dissolves it, and forms underground saline lakes. These form the basis of often small salty ponds, springs, licks, and rivers.

Athalassohaline lakes are most generally formed by the weathering of rocks by wind, rain, and freshwater and were formed during the Pleistocene period and later by volcanic and faulting activity (Hammer, 1986). These are also terminal lakes, and they are typically close to saturation with respect to salt. They may also be ephemeral – found only occasionally after the rainy season – or permanent containing water year round.

The soda lakes are considered athalassohaline because they were formed from high carbonate rocks due to an absence of rocks of sedimentary origins. Consequently, they have low concentrations of calcium and magnesium ions and high concentrations of carbonate or carbonate complexes (Jones et al., 1998).

Biology of saline lakes

Despite the differences in chemical composition, all saline lakes have certain features in common. In general, fish are not found in lakes with salinities greater than 4‰ (40‰). Two major reasons for this are egg survival (Gerking and Lee, 1980) and loss of osmoregulation (Morris, 1960). One exception is the European sea bass, *Dicentrarchus labrax*, which tolerates salinities up to twice that of seawater (Jensen et al., 1998).

Other eukaryotic organisms are found in the higher salinity lakes, specifically algae, brine flies, and brine shrimp. The diversity of the algae depends on the total salt concentration. At salinities lower than around 10–12‰ salt, a wide variety of diatoms and green algae is found. At salinities greater than 12–15‰ and up to saturation, the main algae are from the genus *Dunaliella*. It is also at these higher salinities that the brine fly and brine shrimp are major biomass contributors. These small eukaryotes provide the food sources for the extensive bird populations that are frequently associated with saline lakes. However, other crustaceans such as the mussel shrimp cannot survive in lakes with salinities greater than 18‰ (Deckker, 1981).

Another group of eukaryotic organisms found throughout the range of saline lakes is the fungi. It is only recently that fungi have been isolated from the higher salinity lakes. The state of our understanding of halotolerant and halophilic fungi was summarized by Frisvad (2005). The presence of protozoans and flagellates in saline lakes has also been reviewed and documented by Hauer and Rogerson (2005) and Cho (2005), respectively.

Just as lower salinities allow for a greater diversity of algae, the same is true for the bacteria. Members of the

Domain *Bacteria* predominate in the salinity range of 3–15‰ salt (Ventosa et al., 1998). Above this, the members of the archaeal kingdom domain, the salt-loving *Halobacteriaceae* become dominant though several members of the domain *Bacteria* grow at these elevated salinities. The predominant *Bacteria* genera in elevated salinities are *Halomonas* and *Salinibacter*. As of August 2007, there were 26 described genera of the haloarchaea and 85 species (Oren et al., 2007), and most, but not all, grow over salinity ranges from approximately 12‰ to close to saturation. Microbes found in most salt lakes are therefore, salt-loving and prefer a circumneutral pH.

Among those haloarchaea genera, the “Natrono-” genera are primarily found in soda lakes. As mentioned above, soda lakes have an alkaline pH; therefore, bacteria which grow under those conditions are considered alkaliphiles (alkaline pH-loving). There are many genera of the kingdom *Bacteria* which also contain genera and species that are alkaliphiles. Thus, all of these bacteria are both salt- and high pH-loving organisms. This distinguishes them from the bacteria described in the previous paragraph.

Halophages are viruses that attack bacteria living in saline lakes. The viruses may incorporate into the bacterial cells or they may cause the lysis of the cells. In either case, halophages, like other bacteriophages, tend to be host-specific and can be found wherever their host organism lives. Dyall-Smith et al. (2005) have recently summarized the state of knowledge about the halophages which are specific for the haloarchaea.

Saline lake sediments

Sediments of saline lakes have been the subject of numerous studies because of the potential for determining stable isotope ratios hence sediment age (Piovano et al., 2004) and using lipid biomarkers (Rontani and Volkman, 2005; Pearson et al., 2007) to indicate the types of biota in the sediments. The exposure history of Dead Sea sediments was determined by examining the various minerals formed within the interstitial waters again improving the understanding of the age and depositional history of saline lake sediments (Yechieli and Ronen, 1997). As the salinity of the overlying water increases, this results in similar increases in the salinity of the interstitial waters within the shallow sediments, and the reverse is also true that decreases in the salinity of the lake due to rainfall or snow melt will decrease the salinity of the pore waters.

These postdepositional changes have also been noted for the alkaline Soda Lake in Washington State in the USA (Mantuani, 1973) and in playa Lake Salines in southeastern Spain (Queralt et al., 1997). Such changes can also affect the biology of the sediments which are anaerobic (low to no oxygen) and are dominated by bacterial mats which can produce sulfides and methane (Miller et al., 1993). These mats are composed of layers of bacteria with the cyanobacteria on the surface and various green and purple sulfur bacteria followed by the sulfate-reducing bacteria that produce the sulfides, and the obligately

anaerobic methane-producing bacteria. More recently, Jioang et al. (2007) have noted, in a core from Lake Chaka on the Tibetan Plateau that the distribution of bacteria within the core is determined by the salinity in the pore waters rather than by the mineralogy, and that the biomass decreased most around 150–200 cm depth and increased slightly at 600 cm with a maximum at 900 cm as determined by phospholipid fatty acid analyses. However, the direct counts remained steady with a slight increase at 900 cm. Most of the organisms identified at these lower depths were anaerobic bacteria, again confirming the importance of oxygen to the types of microorganisms found in any sediment.

Value of saline lakes

Saline lakes are nature preserves and serve as home to extensive permanent and migratory bird populations. Great Salt Lake, Utah, USA, hosts over five million birds annually (and this is true in Africa, Australia, the Caribbean, etc.). They may also act as hatching grounds for flamingoes and other birds at the lower salinities. Thus, saline lakes are important in maintaining the biodiversity of our planet.

A second major value, which is related to the first, is that these environments with their large numbers of microorganisms, brine flies, and brine shrimp provide an important gene pool. Although there are numerous studies on the brine shrimp, very little is known about the brine flies, the algae, or the bacteria found in these lakes. Unknown enzymes, potential antibiotics, drug delivery systems, or mechanisms for adaptation to stress could be present but unknown for lack of research into these areas.

Another value of the lower salinity lakes is their potential for aquaculture. Gamito (1997) successfully showed that the gilthead, *Sparus aurata*, could be grown in the Ria Formosa because of the high benthic productivity (1997). Undoubtedly, there are other fish species that could be successfully grown in the lower salinity saline lakes.

A major economic value of saline lakes is their salt. The ephemeral or dried salt beds are a source of salt to many groups of people. This is especially true in Africa with the Taureg people, and in Tibet which also has salt caravans, in the Atacama region of Chile, in Australia, and in Bolivia to name just a few of the places where salt is harvested from dry saline lake beds.

SALINITY HISTORY OF THE EARTH'S OCEAN

L. Paul Knauth
 Arizona State University, Tempe, AZ, USA

Definition

Salinity refers to the total quantity of dissolved salts in water and is normally about 35 parts per thousand (‰) in today's ocean. Due to problems with making accurate measurements of total salts, salinity is now normally

expressed as a ratio of the electrical conductivity of the seawater to that of a standard concentration of KCl solution. The concentration of the standard solution is set such that the ratio of the approximate average salinity of the ocean today is equal to 35. The previous concentration value (‰) is thus unnecessary, but it is still widely used to highlight the basic meaning of the term. The relative proportions of the dissolved constituents are approximately constant, so the amount of Cl^- , the major component, is a proxy for salinity. Salinity history refers to past changes in the amount of dissolved salts in sea water over geologic time.

Significance

Salinity is an important environmental variable affecting chemical balances and osmotic pressures in all living cells. It particularly affects metazoans, because the amount of dissolved oxygen available for respiration depends on oxygen solubility that decreases as salinity increases. Besides its direct effects on cellular biochemistry, salinity governs the temperature of maximum density of sea water and thus the global thermohaline circulation that influences ecosystems. Models of geochemical cycles yield no constraints on past salinity levels, and reliable geochemical proxies, isotopic records, or other possible indicators of ancient oceanic salinity are currently unknown. However, Na^+ and Cl^- constitute about 85% of the salt in the sea, so the geologic record of halite deposits allows insights into how ocean salinity may have varied with time.

Causes of salinity changes with time

Early ideas that steady riverine input of salt to the oceans causes salinity to increase with time failed to recognize the geologic processes that intermittently cause salt to be removed from the sea and then later released following tectonic uplift. Nor did they correctly assess the probable initial origin of salt in the sea or consider possible small changes in ocean volume over time. Salt in rivers is derived largely from groundwater dissolution of ancient marine salt beds deposited when sea water evaporated under arid conditions in low latitude, geographically restricted arms of the sea. Deposition of these “saline giants” depletes the ocean in salt and thus lowers salinity. Subsequently, these enormous deposits may be tectonically lifted above sea level. Depending upon elevation, descending groundwaters can eventually dissolve the deposit and debouch into streams or lodge as dense, saline brines deeper in the continental subsurface. In addition to the saline giants, carbonate depositional environments in shallow seas that flooded the continents in past times typically contained vast tidal flats and supratidal areas in which sea water intermittently evaporated. Partially evaporated sea water from these environments as well as their ephemeral salts dissolved by falling rains descended into the subsurface and lodged in sedimentary basins even where large saline giants were absent. Most large

sedimentary accumulations on continents thus have highly saline waters in the deep subsurface. The salts in these brines were also in sea water once and their sequestration on continents thus also served to lower salinity of sea water. The presence of salt beds and brines hundreds of millions of years old illustrates the enormous lengths of time salt extracted from the sea can remain isolated.

Salinity history for the past 540 Ma

Estimates of the salt inventory in sedimentary rocks have steadily grown as more and more subsurface deposits are discovered. The latest estimate by Hay et al. (2006) confirms that deposition of the saline giants is strikingly episodic (Figure 1). Over half of the salt currently identified was deposited between 100 and 300 million years ago following breakup of the supercontinent Pangea. Presumably, this breakup and subsequent drift of the continental fragments produced the unusual array of geographic, geologic, climatic, and ocean circulation conditions that Sonnenfeld (1984) argued were necessary to produce saline giants. It follows that ocean salinity should have declined during these times of exceptional withdrawal of salts from the sea. The amounts shown in Figure 1 are surely minimal estimates of the amount of salt withdrawn because some significant percentage has been dissolved by groundwaters to become brines in the strata beneath

the salt. Additionally, salt depositional basins are rimmed with clastic deposits adjacent to the surrounding highlands and these are conduits to the subsurface for the prodigious amounts of evaporite brine present when the salt was being deposited. Combined geochemical and isotopic studies have shown that deep basin brines are probably mixtures of partially evaporated sea water and brine created by fresh water dissolution of salt (Knauth, 1988).

Salinity should increase during periods when there are no giant salt extractions underway and when older, uplifted deposits are eroding into the sea. This is the current situation, so the old arguments that the oceans are increasing in salinity via riverine input of salt are understandable. There is no direct evidence yielding the amount of salt returned to the sea at any given past time. Instead, it is necessary to use models for continental sediment erosion that are based on an array of assumptions. Hay et al. (2006) estimate that the return of salt to the sea has varied by a factor of three over the past 540 Ma, reaching maxima in the Upper Cambrian (515 Ma), at the Permian/Triassic boundary (245 Ma), and during the Lower Cretaceous (135 Ma).

Using the inventory of currently sequestered salt and the calculated estimate of salt return, a possible salinity history of sea water for the past 540 Ma can be inferred if the volume history of sea water can be estimated. Fresh basalt on the ocean floors becomes hydrated during subsea

Salinity History of the Earth's Ocean, Figure 1 Salt deposition in the Phanerozoic and estimates of past salinity variations. Ocean salinity declines during deposition of large salt masses. Model estimates by Hay et al. (2006) yield surprisingly high salinity values for the Paleozoic which are not incompatible with values inferred from fluid inclusion measurements by Johnson and Goldstein (1993). Salt masses from estimates by Hay et al. (2006).

weathering and hydrous sedimentary minerals are deposited as the basalt rides tectonic plates to subduction zones. At issue is how much of the hydrated water returns to the surface as it gets progressively heated during subduction. Some models predict a net loss to the mantle over geologic time, so it is not unreasonable to suggest that ocean volumes may have decreased somewhat with time. Combining all these uncertain estimates and models, Hay et al. (2006) have suggested the possible salinity history for the oceans for the past 540 Ma shown in Figure 1. The inferred salinity levels prior to 200 Ma are 50% higher than modern values. Inasmuch as life in the sea is stressed by current salinity values, the idea that Paleozoic life could thrive at such high inferred salinity is likely to be resisted by marine biologists and paleontologists. The amount of brine sequestered during initial deposition and later dissolution remain uncertain and could severely affect such calculated salinity histories. Nevertheless, the provocative Hay et al. (2006) estimates indicate that ocean salinities in the past were likely higher.

Direct salinity measurements in fossil sea water

Tiny fluid inclusions in carbonates or other minerals precipitated directly from ancient seawater may be fossil sea water that could be analyzed for salinity. The difficulty is that the initial precipitates typically undergo dissolution/reprecipitation episodes during subsequent burial and metamorphism. Actual attempts at making this difficult analysis on inferred primary precipitates yield salinities of 31–47‰ at about 500 Ma (Johnson and Goldstein, 1993). These measurements suggest past salinities not too dissimilar from the modern value, but the large error bars do overlap the Hay et al. (2006) estimates (Figure 1). While reliable ancient salinity values remain elusive, it seems demonstrated that significant variations should have occurred in the past 540 Ma and that salinity was likely higher rather than lower in the past.

Salinity history of the early ocean

With regard to deeper time, past salinity can be estimated if it is assumed that the oceans outgassed early in Earth history (Holland, 1978) and that the plate tectonic cycle long ago reached an approximate steady state with regard to hydrosphere cycling through the crust and mantle. Cl^- does not fit readily into any common silicate mineral and thus should have outgassed as HCl along with water following accretion of the Earth. The earliest hydrosphere would thus contain the entire Cl inventory and been at maximum salinity. The only way this high initial salinity can be reduced is by sequestration of salts and brines in the saline giants deposited on long-lived continental cratons. Large continents may have formed shortly after the Earth accreted 4.5 billion years ago (Ga), but recent studies confirm the likelihood that objects in the inner solar system were largely resurfaced by the Late Heavy Bombardment (LHB) at about 3.8–4.0 Ga (Gomes et al., 2005). Continents may have started to reaggregate

following the LHB in the interval between 3.8–2.5 Ga, but the kind of long-lived, continental cratons upon which evaporatively deposited salt and brine could be sequestered following its removal from sea water do not appear until about 2.5 Ga (Rogers, 1996). It follows that all the salt and brine currently lodged on the continents was in the Archean sea following the LHB and prior to the development of these stable cratons.

In the absence of a paleosalinity indicator in the rock record, a reasonable assessment of the earliest salinity could be made if the total amount of salt and brine currently lodged on the continents were known. While the inventory of salt in strata younger than 540 Ma is becoming increasingly better quantified (Figure 1), the amount of salt in older strata is yet to be inventoried. Enormous deposits are known in Neoproterozoic strata (540–800 Ma) across the Middle East, through Pakistan, and into Australia. These apparently accumulated in restricted basins that developed following the breakup of supercontinent Rodinia, analogous to those developed following the breakup of Pangea. The geographic extent of these enormous salt deposits exceeds that of the Cenozoic deposits in the Gulf of Mexico, so it might even be the largest accumulation in Earth history. The amount of subsurface brine associated with the saline giants and with innumerable ancient platform carbonate deposits is also unknown. Land (1995) used estimates of the amount and average salinity of pore fluids to suggest that sequestered brines could hold an amount of salt equal to or greater than that of the rock salt. Adding these amounts of possible total salt and brine currently on the continents back into modern ocean water raises salinity by over a factor of 2. Assuming that the Cl inventory and the oceans were outgassed early in Earth history and have not changed their amounts significantly with time, Archean salinities were therefore much higher and could have exceeded 70‰ (Knauth, 2005).

Implications

The geologic history of salt deposition clearly seems to suggest significant past salinity variations with values possibly much higher than current levels. If so, the impact on biology and biologic evolution must have been significant. An assessment of the paleontologic record in relation to the emerging possible salinity history for the past 540 Ma (Figure 1) remains to be done. The inferred very high salinity of the earliest ocean combined with the probable hot climatic conditions of the early Earth may have limited early marine biologic diversity to the appropriate extremophiles. If the great Neoproterozoic salt deposits were really the first saline giants, the prospect arises that high salinity was prevalent throughout the Precambrian. The great salinity decline likely accompanying deposition of the Neoproterozoic salt combined with declining temperatures associated with probable glaciations may have allowed oxygenation of the ocean for the first time. The Cambrian explosion of life in the sea at 540 Ma may have been, in part, a response of respiring organisms evolving

rapidly in this vast new array of oxygenated marine habitats (Knauth, 2005).

Summary

Salinity is not fixed by any equilibria, feedbacks, or geochemical cycles and appears to have been generally higher in past times. It is apparently a free variable dependent upon the vagaries of intermittent salt (and brine) sequestration on long-lived continental cratons. Ocean salinity declines when the salt and brine accumulate and rises when they are eroded back into the sea. Sequestration seems to have been enhanced following breakup of the two supercontinents in Earth history. These breakups are, in turn, driven by the vagaries of mantle convection. The combination of processes therefore necessary to lower the initial, pre-continent high salinity and to affect the rise and fall of ocean salinity involve a long chain of independent variables. The role of chance and contingency in biologic evolution has long been recognized. The low odds that a rerun of the tape of evolution would yield the same results have been duly noted (Gould, 1990). The same might be said about the evolution of oceanic salinity. Salinity history should therefore probably be added to all those chance occurrences that have likely affected the course of biologic evolution.

SCANNING PROBE MICROSCOPY (INCLUDES ATOMIC FORCE MICROSCOPY)

Michael Hoppert

University of Göttingen, Göttingen, Germany

Synonyms

Atomic force microscopy; Atomic probe microscopy; Force microscopy; Scanning force microscopy

Definition

Scanning probe microscopy uses a nanoscopic probe that is scanned over a solid surface. The interaction between the probe and the surface may be a mechanical or electromagnetic force. The force signal is enhanced and then composed to a force diagram of the surface. Under ideal conditions, an atomic-scale resolution may be achieved.

Introduction

Since their development during the 1970s and early 1980s, scanning probe microscopes (SPMs) have developed into instruments suitable for the analysis of surface topography (and other surface properties) down to near-atomic resolutions. All instruments belonging to this family contain essential components as depicted in [Figure 1](#). In the scanning process, surface material properties are mapped in all three directions. The essential parts of the system are the sharp scanning probe tip, which moves in the *z* direction, a piezoelectric scanner that moves the specimen, or, alternatively, the tip, in the *x/y* directions, and a sensor for tip positioning. Sensor and tip are connected in a feedback loop for the correction of *z* positioning. The *x/y/z* positions are used to generate a topographic image of the specimen. The resolution of SPMs is only limited by the size of the probe tip (or the probe-sample interaction volume). Since the tip apex ends up in one single atom and the piezoelectric actuators execute motions down the range of angstroms, resolutions down to atomic scale are possible. In contrast to electron microscopes, the sample can be observed under ambient conditions, which makes the technique potentially attractive for life science, including geobiological research.

The scanning tunneling microscope (STM)

The scanning tunneling microscope (STM) is the ancestor of all SPMs (Binnig et al., 1982). The specimen needs to be conductive or semiconductive. STM is predominantly used in materials sciences and chemistry. Though not ideally suited for biological specimens, the technique has also been used in life sciences (see, e.g., Guckenberger et al., 1988). The instrument provides a surface topography down to atomic resolution.

STMs use a sharpened conducting tip with a bias voltage (in mV to V-range) applied between the tip and the sample. If the distance between the tip and the sample is large, no current flows. When, however, the tip is brought

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 1 Basic setup of a scanning force microscope.

very close (1 nm), but without physical contact, a small current (pico- to nano-amperes) flows across the gap between the tip and the sample. This current is the result of the overlapping of wave functions between the tip atoms and the surface atoms. Electrons can “tunnel” across the vacuum barrier separating the tip and sample in the presence of the bias voltage. The magnitude of the tunneling current increases exponentially when the tip approaches the specimen surface. This results in high system sensitivity: when the separation between the tip and the specimen changes by 10%, the tunneling current changes by an order of magnitude. This provides, in the end, surface images with lateral atomic resolution. The image of the tunneling current depicts approximately the topography of the sample. Actually, rather than physical topography, the STM measures a surface of constant electron tunneling probability.

Atomic force microscopy and related techniques

Atomic force microscopy (AFM) comprises several derivatives and is applicable for measurement of numerous physical and chemical parameters of sample surfaces. AFM in the strict sense (without a modified probe tip) is used to study the material properties of specimens (stiffness, plasticity, and viscosity; see, e.g., Rotsch et al., 1997). For biological specimens, on the cellular level, the properties of the cytoskeleton and (induced) cytoskeletal changes become visible (see Fung, 1993; Goldmann et al., 1998 for some applications). With the aid of chemically modified tips, AFM is useful for quantification of binding forces between receptors and ligands, protein

complexes and cells (Lehenkari and Horton, 1999; Yip, 2001; Allison et al., 2002; Dufrene, 2008). Since AFM is generally suited for solid surfaces, it is especially a versatile tool for the observation of biomineral formation down to nanoscale in situ (see, e.g., Hildebrand et al., 2008).

Image formation in AFM is generally determined by sensing of interatomic forces, making the technique applicable to all solid specimens. Similar to STM, the AFM probes the surface of a sample with a sharp tip, less than 10 nm in diameter. The tip is located at the free end of a 100–500 μm long cantilever. The cantilever is deflected by forces between the tip and the sample surface, and a detector measures the cantilever deflection as the tip is scanned over the sample (or the sample is scanned under the tip). The measured cantilever deflections are used to generate a map of surface topography (Figure 1). Conductors, semiconductors, and insulators may all be scanned. Resolution in the atomic range requires rigid specimens; hence, for most biological samples (except for biominerals), maximum resolution is not achievable.

The topographic data set necessary for image formation can be directly obtained from the measurement of cantilever deflection. When a laser beam is projected onto the cantilever, the position of the reflected beam is shifted, which results in detection of even sub-nm movement at the tip surface. Other methods of signal enhancement are based upon optical interference (e.g., by a Michelson interferometer). A STM tip may also be used to read the cantilever deflection. If the cantilever is made from a piezoresistive material, its deflection can also be detected electrically.

When the cantilever deflection is detected, this can be used to generate the topographic data set directly. This mode (constant height) is often used for producing atomic-scale images of atomically flat surfaces, for which the cantilever deflections and variations in applied force are small. The constant height-mode is also essential for recording real-time images of changing surfaces, which requires high scan speeds. Alternatively, the deflection of the cantilever can be used in a feedback loop that moves the scanner up and down in the z direction, responding to the topography, by keeping the cantilever deflection constant. In this case, the image is generated from the scanner's motion. With the cantilever deflection held constant, the total force applied to the sample is constant. This mode (constant force) is generally preferred for most applications.

Figure 2a depicts the typical force–distance curve for AFM. As the atoms of the tip and the specimen surface are gradually brought together, they first weakly attract each other by van der Waals forces. This attraction increases until the electron clouds of the atoms are so close together that their electrostatic repulsion progressively weakens the attractive force. The force becomes zero when the distance between the atoms reaches a couple of ångströms, about the length of a chemical bond. In the *contact mode*, the cantilever is held less than a few ångströms from the sample surface, and the interatomic force between the cantilever and the sample is repulsive. For biological (i.e., soft and wet) objects, the contact mode may induce several artifacts. This is avoided by application of modes in which less force is applied to the specimen. However, smaller forces also have to be detected, which in practice reduce the final resolution. In the *noncontact mode*, the cantilever is held of the order of tens to hundreds of ångströms from the sample surface, and the

interatomic force between the cantilever and sample is attractive (largely as a result of long-range van der Waals interactions). In this mode, the cantilever is oscillated with a frequency of 100–400 kHz (the resonance frequency of the cantilever) with an amplitude of a few tens of nanometers. The resonance frequency of the cantilever varies with the force gradient acting on the cantilever. These variations can be used as a measure of changes in the force gradient, which in turn reflects the changes in the tip-to-sample distance, or sample topography. The resonant frequency or vibrational amplitude of the cantilever is monitored and kept constant with the aid of the feedback loop that moves the scanner up and down in the z direction. The system also keeps the average tip-to-sample distance constant. As in contact AFM (in constant-force mode), the motion of the scanner is used to generate the topographic data set. It thus detects changes in the resonant frequency or vibration amplitude as the tip comes near the sample surface. *Intermittent-contact* (or tapping mode) AFM is similar to noncontact AFM, but the vibrating tip is brought closer to the sample in such a way that the sample is intermittently contacted or “tapped.” As in noncontact AFM, the oscillation amplitude of the tip also changes in response to the distance between tip and sample. Intermittent-contact AFM is also less likely to damage the sample than contact AFM. Though it touches the specimen, lateral forces (friction or drag) between the tip and the sample are minimal. The *pulsed force mode* (PFM) is used to monitor, besides sample topography, stiffness and adhesion simultaneously (Krotil et al., 1999). In PFM, the probe scans the surface in contact mode. When the cantilever is oscillated with a frequency of about 1 kHz, it is possible to analyze the force output as a function of the distance between the tip and the surface. The force output is depicted in Figure 2b. During an oscillation

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 2 (a) Force–distance curve in atomic force microscopes. (b) Force curve in the pulsed force mode (PFM). Important features of the curve are marked with blue dots.

cycle the probe tip is attracted by the surface and “snaps” into contact at a certain distance. The tip is then pushed further to the sample, the force signal increases, whereby the slope of the curve depends on the specimen stiffness. When the distance increases, force signal decreases, the tip loses contact (adhesion peak) and oscillates freely until the signal is damped to the baseline. Characteristic points of these curves are taken for processing to generate simultaneous topographic, stiffness (deformation of the specimen under an applied force), and adhesion maps. In the lateral force mode (LFM), lateral deflections (twisting) of the cantilever are measured. These are caused by forces on the cantilever parallel to the plane of the sample surface. LFM studies are used to detect surface friction arising from inhomogeneity in surface material; an artificial enhancement of edges in the image may also be achieved (Overney et al., 1992). In the force modulation mode (FMM), the elastic properties of a specimen are mapped. The cantilever tip is scanned in contact with the sample surface. As in constant-force contact AFM, the feedback loop uses the cantilever deflection signal to maintain a constant force between the tip and the sample and to generate a topography image. When a periodic oscillation is applied to the tip or the sample, the sample surface resists and the cantilever bends according to the elastic properties of the sample surface. The system generates an image, a map of sample stiffness, from the changes in the amplitude of cantilever modulation (Troyon et al., 1997).

Scanning force microscopy is a highly variable technique, because forces between a specimen and an AFM tip may be caused by a multitude of underlying factors. A modified scanning tip may therefore be used to measure a variety of parameters other than the described surface forces. In life sciences, the detection of chemical properties on biological surfaces is of outstanding interest. Some derivatives of AFM, mainly based on a modified scanning tip, are listed below.

Magnetic force microscopy (MFM) is used for measuring the magnetic force between the tip and the sample. For MFM, the tip is coated with a thin ferromagnetic film. The system mostly operates in noncontact mode and detects magnetic domains down to a resolution of approximately 20 nm (de Lozanne, 2006).

Electrostatic force microscopy (EFM) measures the forces originating from an electrical field between the AFM tip and the sample. When a voltage is applied between the tip and the sample (the tip is not in contact with the surface), the cantilever deflects when it scans over charged particles on the sample surface. In this way, EFM maps locally charged domains on the sample surface (Girard, 2001).

Scanning thermal microscopy (SThM) measures the specimen temperature and thermal conductivity of the sample surface. The SThM tip may be made from a thermocouple temperature sensor: a pair of dissimilar metals joined at the tip (platinum/silver Wollaston wires). The temperature difference between the tip and the open end generates a proportional net voltage. In this way, thermal

data and surface topography (with the conventional AFM force feedback mechanism) can be measured at the same time. Probes made of Wollaston wires also operate as active heat sources. The probe resistance is proportional to the probe temperature. Changes in the current required to keep the probe at constant temperature produce a thermal conductivity map. When the tip is held at a constant current, the specimen temperature is mapped by changes in the probe resistance (Price et al., 1999).

Photothermal microspectroscopy (PTMS) combines scanning probe microscopy at a submicron spatial resolution with an IR interferometer. IR radiation from a Fourier-transform spectrometer is focused on a specimen. IR absorption causes stretching and bending of molecular bonds. Upon relaxation of these molecular vibrations, evanescent thermal waves are emitted. This signal is detected with a Wollaston wire (SThM) probe. The resulting temperature fluctuations are converted to electrical signals, recorded as a function of time and amplified to produce an “interferogram” which can be transformed back to give a conventional spectrum as in other forms of FTIR spectroscopy. In PTMS, resolutions down to 10 μm are achievable, whereas in conventional FTIR microspectrometric devices, only 100 μm are possible (Grude et al., 2007).

Phase detection microscopy (PDM) is another variation for mapping of surface properties such as elasticity, adhesion, and friction. Unlike FMM (see above), the technique operates in the noncontact mode, which is more suitable for less rigid (biological) samples. The technique monitors the phase lag between the signal causing the cantilever to oscillate and the cantilever oscillation output signal. Changes in the phase lag reflect changes in the mechanical properties of the sample surface. The feedback loop in PDM operates in the usual manner, using changes in the cantilever’s deflection or vibration amplitude to measure sample topography. The phase lag is monitored while the topographic image is being taken, so that images of the topography and material properties can be collected simultaneously.

Scanning near-field acoustic microscopy (SNAM) utilizes an ultrasonic quartz oscillator as resonator and at the same time as a sensor of the damping force exerted by the specimen. Damping increases when the tip approaches the surface. The instruments have been especially developed for scanning of larger areas, with a surface relief in the millimeter range. For low resolution, wide probing tips are used. At resolutions of 100 nm, both hard and soft specimens are well suited for mapping. Higher resolution is obtained with sharp AFM tips (Murdfield et al., 1996).

With chemical force microscopy (CFM) it is possible to obtain modified force curves based on specific interactions between molecules on the specimen surface and a sensor molecule on the probe tip. The tip (normally made from silicon or silicon nitride) is modified by coating a very thin metallic film (normally a 5 nm thick chromium layer followed by a 50 nm thick gold layer) onto the probe, followed by immersion of the probe in a solution of an

organic thiol. The molecules form a monolayer, with the thiol group bound to the gold surface. The distal end of thiol molecule contains an appropriate functional group for interaction with the sample surface. Besides small methyl, carboxyl or amino groups, macromolecules may also be used as specific probes. Coupled enzyme proteins may be used to measure enzyme–substrate interactions. In a similar experimental setup, even whole bacterial cells, coupled to the cantilever, were used to measure distance–force curves between the cell surface and biominerals (Lower et al., 2001; Dufrene, 2008 and references therein).

Near-field scanning optical microscopes (NSOMs) are based upon the AFM operating in the noncontact mode. At the same time, the probe tip generates nonpropagating (evanescent) electromagnetic wave fields to excite a specimen at a small (down to tens of nm) surface spot. Most NSOM setups use an aluminum-coated glass fiber with a sub-light wavelength aperture (25–100 nm in diameter) at the tip of an AFM-like scanning probe (Figure 3). Light, guided through the fiber optics, causes an evanescent wave field that decays exponentially with distance from its origin. Evanescent waves interact with the specimen surface, e.g., by excitation of fluorophores. Fluorescence light emitted from the specimen is scattered from the sample, but only from the evanescent wave field region (at distances from the probe tip of approximately one fifth of the light wavelength). The fluorescence signal is conventionally propagating far-field light. This signal may be collected by a conventional optics below the specimen (e.g., an inverted microscope). Because of the extremely small excitation volume determined by the evanescent wave, together with the high-resolution topographical map generated by the AFM tip, a high-resolution map of the fluorescent targets in the specimen is achieved.

With NSOM, the AFM topographic information is combined with optical properties of a specimen, such as

Scanning Probe Microscopy (Includes Atomic Force Microscopy), Figure 3 Hollow fiber tip in a near-field scanning optical microscope (NSOM). At the tip, the evanescent wave field (red) excites a fluorophore marker (yellow). The resulting (far-field) light signal is detected by an external detector. Propagating far-field light (orange arrows).

refraction index, reflectivity, transparency, polarization Raman shift, and fluorescence (Gheber et al., 1998; de Lange et al., 2001; Edidin, 2001).

Conclusion

Scanning probe microscopy introduced a purely surface-related technique with atomic resolution into the field of material sciences and also life science. For the first time it was possible to visualize macromolecules directly, under physiological conditions. Even more important is the application potential for mapping all kinds of intermolecular interactions. The fact that just signals from a surface can be collected may be a drawback for the observation and documentation of most biological processes because they are inside cells and other compartments. Most mechanisms in material science, chemistry and biology are, however, surface-related. It is just the question how a surface, which may also be a membrane or the interface of another compartment, can be prepared in a way that it is reachable by an SPM.

Other limitations are the low scanning speed of most modes and the small obtainable image area. Hence, it is straightforward to combine scanning probe microscopy with other imaging techniques. Correlation of low-resolution techniques including fast image acquisition (fluorescence light microscopy or confocal microscopy) with the high-resolution AFM image may be versatile for a multitude of applications, especially concerning the interaction of organisms with solid surfaces (e.g., Arnold et al., 2004; overview in Haupt et al., 2006).

SEDIMENT DIAGENESIS – BIOLOGICALLY CONTROLLED

Kurt O. Konhauser¹, Murray K. Gingras¹, Andreas Kappler²

¹University of Alberta, Edmonton, Alberta, Canada

²University of Tübingen, Tübingen, Germany

Definition

The biological processes that modify unconsolidated sediment after initial deposition and burial.

Overview

Throughout the sediment column, up to the temperature threshold of life, microbial activity plays an integral role in diagenesis. It is widely recognized that through their various chemoheterotrophic pathways, microorganisms are ultimately responsible for the conversion of organic carbon to CO₂ and CH₄ at temperatures <100°C. Some aerobic bacteria use hydrolytic enzymes to break down complex molecules into simple monomers such as sugars, amino acids, and fatty acids that they can then utilize, while most anaerobes are restricted to simple organic compounds (e.g., acetate, lactate, H₂) that are the by-products of fermentation (Lovley and Chapelle, 1995). Typically, the more labile materials (e.g., proteins, carbohydrates) are degraded in near-surface sediments on time scales of days to years, and more refractory materials (e.g., lipids) are broken down deeper in the sediment on time scales of decades, while the most resistant materials (lignins) are transformed only on timescales of thousands to millions of years. The amount of refractory material left after microbial attack will depend on the nature of the primary producers and the degree of processing that has taken place in the river catchment area or oceanic water column. In the end, for example, <1% of the original material buried into marine sediment may ultimately contribute to the sedimentary organic geochemical record (Emerson and Hedges, 1988).

Pore water and mineralogical changes during diagenesis are directly related to bacterial reduction of soluble (O₂, NO₃[−], SO₄^{2−}, CO₂) or solid-phase (MnO₂ and ferric oxyhydroxides) components in the sediment. The terminal electron accepting processes (TEAPs) that occur at any given layer depends on oxidants that are available and, in the situation when multiple electron acceptors are present (as in the uppermost sediment layers), on the free energy yield of the specific reaction. Thus, the decomposition of freshly deposited organic material in sediments proceeds in a continuous sequence of redox reactions, with the most electropositive oxidants being consumed at, or near the surface, and progressively energetically poorer oxidants being consumed at depth until the labile organic fraction is exhausted and the deeper sediments are left with a composition very different from that of the sediments originally deposited (Figure 1). Inorganic by-products of chemoheterotrophy (e.g., HCO₃[−], Mn²⁺, Fe²⁺, NH₄⁺, NO₂[−], HS[−], HPO₃^{2−} and CH₄) seldom accumulate. Physical and macrofaunal processes will cause the net transport of these reduced species from the deeper layers toward the sediment surface, where residing anaerobic and aerobic chemolithoautotrophic bacteria use them as metabolic reactants. Alternatively, their presence in pore waters may trigger important abiotic reactions between the solid and dissolved phases leading to secondary mineral formation, i.e., cementation.

Oxic zone reactions

The sediment–water interface is the site of most intense heterotrophic activity. Aerobic respiration (Reaction 1) is

Sediment Diagenesis – Biologically Controlled, Figure 1 Idealized pore water and solid-phase profiles based on the successive utilization of terminal electron acceptors during the decomposition of marine sedimentary organic matter. (From Konhauser 2007.)

the first used metabolic pathway for the degradation of organic matter, not only because it has the greatest energy yield per amount of organic carbon oxidized, but the aerobes are equipped with a full suite of extracellular enzymes capable of degrading complex organic polymers into simpler substrates (e.g., cellulose into glucose).

$$\Delta G^0 = -2872 \text{ kJ/mol glucose or } -240 \text{ kJ/2e}^-$$

It is estimated that on a global scale, the majority of all particulate organic carbon (POC) deposited is aerobically respired; the percentage varies among different marine environments, with aerobic respiration accounting for >90% of the organic carbon oxidized in deep sea sediments (e.g., Bender and Heggie, 1984), while O_2 is the TEA in only 45% of coastal marine settings and freshwater lakes (e.g., Jones, 1985).

In marine sediment, one of the primary factors controlling the patterns above is the composition of the organic material and the rate at which it is deposited. Plankton-derived organic matter, rich in lipids and cellulose, exhibit significantly higher reactivities than land-derived organic material consisting of vascular plants rich in lignins (Hedges et al., 1988). Thus, in coastal settings, a significant fraction of POC may be relatively difficult

to decompose. Furthermore, under the high deposition rates characteristic of coastal settings (1 mm year^{-1}), O_2 diffusion is very shallow and the oxic zone may only extend down a few millimeters in depth, although physical stirring of surface sediments by waves and currents, circulation of overlying water through animal burrows that are connected to the sediment–water interface (known as irrigation), and bioturbation of surface sediments may locally increase the depth to several centimeters (e.g., Hammond et al., 1985). Therefore, with high accumulation rates, freshly deposited organic matter passes through the oxic zone on the orders of 1–10s of years, leaving a significant amount of carbon intact to support fermentative and anaerobic heterotrophic populations (Canfield, 1993). By contrast, the influx rate of POC and nutrients decreases with distance from land and water depth. This results in a progressive diminishment of macrofaunal and planktonic species, as well as the benthic bacterial populations, leading to low organic matter accumulation rates in the deep sea. Coupled with the low sedimentation rates associated with the open ocean ($<0.01 \text{ mm year}^{-1}$), the organic fraction will remain exposed to oxygenated waters for thousands of years, leading to almost complete oxidation by O_2 – only the most refractory fractions will remain available for other TEAs in the deeper sediments (Murray and Grundmanis, 1980).

O₂ is also consumed by a vast number of chemolithoautotrophic bacteria that metabolize upwardly diffusing reductants (such as HS⁻, NH₄⁺, Fe(II)). Therefore, as reduced metabolites from anaerobic respiratory pathways diffuse upward, a fraction of the oxygen consumed in the surface layers is diverted away from aerobic respiration, toward reoxidation of the reduced species. As a consequence, the depth of O₂ penetration correspondingly decreases. In fact, some diagenesis models show that the amount of O₂ partitioned to organic carbon oxidation in coastal sediments can be <1%, with nitrification or hydrogen sulfide oxidation comprising the major O₂ sinks (e.g., Blackburn and Blackburn, 1993).

Suboxic zone

Nitrification–denitrification

Nitrogen cycling in aquatic sediments is relatively complex, with nitrate pore water concentrations governed by the balance between nitrification in the oxic zone and denitrification in the suboxic zone. The amount of nitrification is regulated by the concentration of pore water ammonium (NH₄⁺), which largely depends on the C:N ratio of the sedimentary organic carbon being oxidized, and the amount of O₂ penetration (Blackburn and Blackburn, 1993). In the presence of O₂, ammonium is first oxidized to nitrite by ammonium-oxidizing bacteria (e.g., *Nitrosomonas* sp.), and the nitrite is then further oxidized to nitrate by nitrite oxidizers (e.g., *Nitrobacter* sp.). Collectively, these processes (Reaction 2) cause a subsurface peak of nitrate in the pore water (Mortimer et al., 1999).

The opposing processes in marine N-cycling is denitrification (loss of NO₃⁻ to N₂) and nitrate ammonification (loss of NO₃⁻ to NH₄⁺). Denitrifiers most closely resemble aerobic respirers in that they are capable of completely degrading complex organic matter to carbon dioxide (Reaction 3).

$$\Delta G^0 = -2715 \text{ kJ/mol glucose or } -226 \text{ kJ/2e}^-$$

In coastal sediments (and lakes), these bacteria reduce nitrate to negligible levels within 1–10 cm of the sediment–water interface. No nitrate occurs below this depth except where burrows, lined with nitrifying bacteria, irrigate oxygenated water to depths well below the oxic–suboxic boundary (Hansen et al., 1981). In deep sea sediment, the vertical zone of all terminal electron acceptors (TEAs) are expanded, and for nitrate, concentrations may not become negligible until depths of >1 m. Denitrification fluxes range over several orders of magnitude in marine sediments, between values as low as 1 μmol m⁻² day⁻¹ in deep sea sediments (Bender and Heggie, 1984)

and over 1 mmol m⁻² day⁻¹ in some estuarine and coastal waters (e.g., Devol, 1991).

The flux of N₂ escaping from sediments is often higher than predicted biological or inorganic denitrification rates based solely on pore water nitrate concentrations. This means that in the sediments, excess N₂ is being formed independent of a nitrate intermediate. One way this occurs is through the anammox process, where shunting nitrogen directly from ammonium to N₂ (Reaction 4) can promote ammonium deficiencies in sediments where this process plays a key role in nitrogen cycling (Thamdrup and Dalsgaard, 2002).

Ammonium can also react inorganically with MnO₂ to form N₂ instead of nitrate (Reaction 5). The Mn(II) formed in this reaction is biologically oxidized by Mn(II)-oxidizing bacteria (see below), with O₂ as the TEA, generating more reactive MnO₂ to continue the oxidation of the soluble ammonium (Luther et al., 1997). Field evidence suggests that this reaction can outcompete the direct oxidation of NH₄⁺ by O₂ to NO₃⁻ in Mn-rich coastal sediments, and in doing so, potentially account for 90% of N₂ formation. In essence, this process short-circuits the traditionally considered nitrification–denitrification process.

Manganese cycling

Detrital mineral phases that survive transport and deposition are for the most part an unreactive component of the bottom sediment. The oxides and hydroxides of manganese and iron are the exceptions. These phases are stable under the oxygenated conditions encountered in the water column, but they quickly become unstable after burial below the oxic layers of sediment. Following denitrification, reduction of Mn(IV) oxides (typically written as MnO₂) to dissolved Mn²⁺ becomes the most energy-efficient bacterial respiratory process (Reaction 6).

$$\Delta G^0 = -558 \text{ kJ/mol acetate or } -139 \text{ kJ/2e}^-$$

In most sediments, the limited amount of manganese (and iron) oxides deposited in sediment, as well as the slower rates of burial of these oxides compared to the downward diffusion of O₂, NO₃⁻ and SO₄²⁻, generally makes their reduction of minor importance (<10%) in terms of the amount of total organic carbon oxidized (Burdige, 1993). There are, however, exceptions to this generalization, i.e., some lakes and marine hydrothermal settings where high rates of metal oxide reduction are driven by a combination of relatively high metal inputs and active macrofaunal activity that mix suboxic sediment with

oxygenated bottom waters, thereby reoxidizing dissolved Mn^{2+} (and Fe^{2+}) to MnO_2 or $\text{Fe}(\text{OH})_3$ (Aller, 1990).

In typical marine sediments, the concentration of Mn^{2+} is negligible at the sediment surface, but at some depth between the NO_3^- maximum and zero NO_3^- , it begins to increase toward its maximum values. Despite forming near the base of the nitrate reduction zone, its concentration is never highest at that depth because the $\text{Mn}(\text{II})$ that diffuses upward is biologically reoxidized and precipitated as fresh MnO_2 at the sediment surface, suggesting that the TEA can be either nitrate or oxygen (Froelich et al., 1979). A characteristic feature of $\text{Mn}(\text{II})$ oxidation is the upward convexity of the pore water Mn^{2+} profile and the discrete layer of MnO_2 forming at the base of the oxic zone (recall Figure 1). By contrast, downward diffusion of $\text{Mn}(\text{II})$, and its reaction with HCO_3^- , most commonly results in the formation of manganese carbonates, such as rhodochrosite (MnCO_3).

Iron cycling

Below the zone of dissimilatory manganese reduction, and at the depth of complete nitrate removal from pore waters, is where $\text{Fe}(\text{III})$ reduction takes place (Reaction 7). Ferrihydrite [$\text{Fe}(\text{OH})_3$] is the least crystalline, most reactive, and easily reducible iron oxide phase, with rates of $\text{Fe}(\text{III})$ reduction in sediment declining rapidly with depth as these poorly crystalline phases become depleted (Lovley and Phillips, 1986).

$$\Delta G^0 = -337 \text{ kJ/mol acetate or } -84 \text{ kJ}/2\text{e}^-$$

Despite the lower reactivity of crystalline phases, in sediment where ferrihydrite has either been depleted or where crystalline iron oxides are inherently more abundant, the latter can serve as significant source of reducible iron that couples the oxidation of buried organic material. According to experimental observations, $\text{Fe}(\text{III})$ -reducing microorganisms developed three different strategies to cope with the difficulty of transferring electrons from the cell to the surface of a barely soluble electron acceptor (see Lovley et al., 2004 for review). First, physical contact between the cell surface and ferric iron allows direct delivery of electrons. Second, iron chelators increase the solubility of $\text{Fe}(\text{III})$ and hence, alleviate the need for $\text{Fe}(\text{III})$ reduction. Third, electron-shuttling compounds transfer electrons from the cell to $\text{Fe}(\text{III})$ oxide surface without the necessity of physical contact between cells and mineral. Considering the complexity of natural environments and the wealth of microbial capabilities, it is not surprising that different organisms, as well as single organisms, developed different strategies in order to reduce diverse $\text{Fe}(\text{III})$ compounds under varying conditions. For example, some evidence indicates that *Geothrix fermentans* produce and release both $\text{Fe}(\text{III})$ chelators and electron

shuttles (Nevin and Lovely, 2002). Furthermore, studies on *Geobacter* sp. indicate that different cellular compounds are involved in reduction of dissolved $\text{Fe}(\text{III})$ -citrate and barely soluble ferrihydrite (e.g., Leang et al., 2005).

The reduction of ferric iron minerals increases the concentration of $\text{Fe}(\text{II})$ in suboxic sediment pore waters, with a peak in concentration at the boundary between the $\text{Fe}(\text{III})$ and sulfate reduction zones. Some of this ferrous iron may diffuse upward to be reoxidized to ferric hydroxide inorganically by either NO_2^- , MnO_2 , or O_2 (e.g., Myers and Nealson, 1988), and it is likely that in some lakes with near-surface sediment, phototrophic $\text{Fe}(\text{II})$ oxidation should take place. Some $\text{Fe}(\text{II})$ also precipitates as mineral phases. In iron-rich sediments, the high reactivity of Fe^{2+} and the general availability of HCO_3^- in suboxic and anoxic pore waters tend to cause ferrous iron to precipitate quickly as micritic cement in the form of siderite (FeCO_3). By contrast, when sulfate reduction rates exceed $\text{Fe}(\text{III})$ reduction rates (see below), enough HS^- is produced to react preferentially with any ferrous iron to precipitate iron monosulfide minerals instead (FeS has lower solubility than FeCO_3). Therefore, the precise juxtaposition of iron reduction and sulfate reduction in marine sediments controls the formation of siderite and/or pyrite (e.g., Coleman, 1985). The formation of vivianite [$\text{Fe}_3(\text{PO}_4)_3$] in many ways resembles that of siderite, namely $\text{Fe}(\text{II})$ concentrations must exceed those of HS^- . It also requires that soluble phosphate is made available through oxidation of organic matter, the dissolution of phosphorous-bearing solid phases, or through reduction of phosphorous-adsorbing $\text{Fe}(\text{III})$ oxides (Krom and Berner, 1980).

Anoxic zone

Sulfate reduction

Below the suboxic layers is a highly reducing, oxygen-free zone under which sulfate reduction predominates. In marine sediments, this is the principal process by which simple fermentation products are oxidized (Reaction 8), accounting for approximately 50% of the carbon oxidation in coastal marine sediments (Jørgensen, 1982), but <10% in deep sea and freshwater environments (Bender and Heggie, 1984; Jones, 1985).

$$\Delta G^0 = -49 \text{ kJ/mol acetate or } -12 \text{ kJ}/2\text{e}^-$$

Its relative importance in marine environments compared to freshwater environments is based simply on the higher concentrations of dissolved SO_4^{2-} (~28 mM) at the sediment–water interface, some 50 times greater than the combined sum of all other electron acceptors with higher electrode potentials. Moreover, external electron acceptors that yield more energy than SO_4^{2-} typically disappear within the first few centimeters of sediment depth, leaving sulfate as the dominant TEA for most of the sediment column (D'Hondt et al., 2002).

The rates of dissimilatory sulfate reduction are proportional to the quantity and reactivity of organic matter entering the anoxic sediments – the greater the amount of aerobic decomposition, the less labile organic matter remains available for sulfate reduction, and the more refractory the residual material becomes (Westrich and Berner, 1984). As a result of natural variations in the above, sulfate reduction rates in marine sediments can vary by six orders of magnitude, with the highest in rapidly deposited coastal and lagoonal sediments, where it occurs just below the sediment–water interface ($>1 \text{ mM cm}^{-2} \text{ year}^{-1}$) and at the lowest levels in deep sea sediments, where rates may be $<10^{-5} \text{ mM cm}^{-2} \text{ year}^{-1}$ (Canfield, 1993).

The product of sulfate reduction is hydrogen sulfide, and as mentioned above, can lead to the formation of iron sulfide minerals. The amount and reactivity of the detrital iron phases dictate the amount of pyrite that will form, commonly referred to as the “degree of pyritization.” In slowly accumulating sediments (i.e., the deep sea), little labile organic matter is buried, sulfate reduction rates are slow, less HS^- is available for reaction with detrital iron, so less ferric iron is eventually converted to pyrite. Since the saturation state of the pore waters with respect to iron monosulfides controls the pore water concentrations of dissolved iron and sulfide, limited HS^- means that pore water Fe(II) will increase in concentration. By contrast, in rapidly accumulating sediments, more labile organics are buried, near-surface sulfate reduction rates are high, HS^- is abundant, and more of it is available for reaction with dissolved Fe(II) and solid-phase ferric iron (Berner and Raiswell, 1983). Nonetheless, not all ferric iron phases are pyritized because some ferric iron minerals react only very slowly with dissolved sulfide, and complete pyritization becomes impossible in the time span over which sulfate reduction occurs in the sediment (Canfield et al., 1992).

Only a fraction of the HS^- that forms via bacterial sulfate reduction is actually precipitated as pyrite sulfur (Berner, 1982). Instead, some 90% of the HS^- is reoxidized to sulfate. Although O_2 , NO_3^- , and Mn(IV)- or Fe(III)-oxides are the ultimate oxidants in sedimentary systems, there exists a dynamic S-subcycle that involves a number of sulfur intermediate products, with thiosulfate appearing to be the most significant (Jørgensen, 1990). In addition, some of the HS^- that ultimately escapes the thio-sulfate subcycle provides a useable source of reducing power for various chemolithoautotrophs, most of which gain energy from oxidizing sulfide, with O_2 as the TEAP (Reaction 9).

Methanogenesis

The terminal step in the anaerobic degradation of organic material is methanogenesis (Reactions 10 and 11). As the least energetically favorable process of organic

degradation, the reaction product, methane (CH_4), actually stores a major part of the energy available for aerobically respiring species, i.e., methanotrophs.

$$\Delta G^0 = -31 \text{ kJ/reaction}$$

$$\Delta G^0 = -34 \text{ kJ/reaction}$$

On average, methanogenesis is responsible for 5–10 times less organic carbon degradation than sulfate reduction, and it is only important in sediments where a significant amount of relatively fresh organic material is delivered rapidly enough to pass through the sulfate reduction zone that it takes on any prominence (Canfield, 1993). Indeed, methane does not accumulate in sediments until more than 90% of the dissolved sulfate has been reduced (Martens and Berner, 1974). This is unsurprising given that the growth of methanogens is inhibited by SRBs, because the latter have a higher affinity for the oxidizable substrates than do the former (Lovley et al., 1982). In other words, methanogens prosper when subsurface activity of SRBs is high and pore water SO_4^{2-} becomes diminished.

The CH_4 generated by methanogens in the underlying sediment subsequently diffuses upward toward the sulfate-rich sediments, where it serves as an electron donor in the sulfate–methane transition zone (SMTZ) (Reaction 12).

In some marginal marine sites, it has been estimated that nearly 100% of the downward SO_4^{2-} flux and the upward CH_4 flux can go toward anaerobic CH_4 oxidation. Comparison of these fluxes to open ocean sites even suggests that anaerobic methane oxidation might be the dominant sink for sulfate in marine sediments relative to organic carbon oxidation (D'Hondt et al., 2002). The diffusive flux of CH_4 upward is usually inadequate to completely reduce pore water sulfate, and hence, accumulate above the SMTZ. Yet, it has been observed in some rapidly depositing shallow water sediments that methane saturates pore waters and ultimately may escape the sediment by bubble ebullition, without complete oxidation by sulfate (Martens and Klump, 1984).

Sediment hydrogen concentrations

As discussed above, the dominant terminal electron accepting pathways in sediments are generally segregated into distinct zones based on the potential thermodynamic yield of the various metabolic processes. Yet, on a purely thermodynamic basis, reactions yielding less energy should also take place as long as they are energetically favorable. Instead, the segregation can be more accurately explained by competition between different types of

microorganisms for electron donors, such as the fermentation products H_2 and acetate (Lovley and Klug, 1986). Accordingly, microorganisms utilizing electropositive TEAs effectively maintain H_2 concentrations below the capabilities of microorganisms using TEAs that yield less energy, and it is only when the electropositive TEA becomes depleted that the next most electropositive TEA controls the H_2 concentrations in the pore water system (Lovley and Goodwin, 1988). In pore waters, this translates into distinct H_2 concentration gradients for each particular metabolism and a threshold level below which H_2 cannot be further metabolized. When nitrate and manganese reductions are the dominant terminal electron accepting pathways, pore water hydrogen concentrations are extremely low (<0.05 nM), with increasing levels through iron reduction (0.2 nM), sulfate reduction (1–1.5 nM), and methanogenesis (7–10 nM). Acetate concentrations follow a similar pattern (Chapelle and Lovley, 1992).

This pattern of H_2 and acetate competition can be ascribed to the physiological capabilities of the microorganisms growing in the sediments. Microorganisms that use amorphous ferric hydroxide as their TEA can metabolize H_2 or acetate to concentrations lower than those that can be utilized by sulfate reducers, and the sulfate reducers can metabolize the same substrates to concentrations below those usable by methanogens (Lovley and Phillips, 1987). These findings are consistent with observations of sediments where sulfate is not reduced, and methane is not produced until the reducible ferric iron minerals have been converted to Fe(II). Given the pattern above, it is not surprising then that the availability of NO_3^- or Mn(IV) oxides diminishes the magnitude of Fe(III) reduction in suboxic sediment, and under such conditions, some of the Fe(III) reducers may even switch over to nitrate or manganese reduction when H_2 becomes limiting for them under their normal mode of growth (Lovley and Phillips, 1988; diChristina, 1992).

Macroscopic biological influence on diagenesis

On the seafloor, recently deposited sediment is subject to grazing, burrowing, and particle reworking by relatively large animals moving over the surface of the sediment and the more numerous small organisms and microorganisms living within the upper layers of sediment. This influence may extend several decimeters (and even meters) below the sediment–water interface, but their effect is largely concentrated in the uppermost 20 cm. The benthos are typically inhibited when (1) the particulate organic supply is too low; (2) when the sediment is too fine-grained and compacted to provide sufficient space for them to live, (3) when O_2 levels reach values <0.2 mg l^{-1} , and (4) when strong ebb and current flows quickly redistribute sediment for burrows to become established (e.g., Van Cappellen and Gaillard, 1996).

Burrowing organisms biomechanically and geochemically alter sediments – a process generally referred to as

bioturbation – in spatially intricate ways. Biomechanical modification includes the redistribution of grain sizes and the modification of grain size and sediment cohesiveness. It also impacts on the organic properties of the sediment because grazing causes greater disintegration of intact organic remains, leading to higher surface areas for microbial oxidation, while burrowing mixes fresh organic matter with older, more decomposed materials, causing enhanced degradation of the latter. Ingestion of refractory organic carbon may lead to excretion of more labile fecal pellets (Lee, 1992). The style of biomechanical deformation can be variable depending on the intrusive process employed by the burrowing animal. In clastic sediments, the redistribution of sediment grain sizes strongly influences the arrangement of permeability pathways, thereby exerting a control on the flux of pore water near, and within, preserved burrows. Through abrasion and ingestion, carbonate sediments are prone to (biogenic) grain-size reduction. This provides a more reactive medium for diagenetic fluids to react with.

The biochemical modification of sediment is the result of local compositional heterogeneity imposed by biogenic structures. This includes an increase in the surface area at the sediment–water interface, which in turn, increases the rate and amount of chemical exchange between the sediment, the pore water, and the water column. For instance, irrigation of worm burrow tubes with oxygenated seawater results in increased downward and lateral diffusion of O_2 into surrounding sediment and concomitantly the loss of sulfur from the sediment by oxidation of pyrite and enhanced diffusive loss of HS^- (Bernier and Westrich, 1985). Subsurface flushing with oxygenated waters also influences nitrification, Mn(II)- and Fe(II)-oxidation patterns. In the case of iron cycling, as long as ferric iron persists, phosphate remains adsorbed to the oxide surface and is thus unavailable to the pore waters. Meanwhile, the incorporation of concentrated (and typically labile) organic material in the form of mucus or feces not only provides an oxidizable substrate for the microbial communities, but also leads to concentration of metals in, and adjacent to, burrow linings as sorbed cations or as metal oxyhydroxide, sulfide, or phosphate coatings (Over, 1990). These metals may then serve as nucleation sites for authigenic mineral formation, which provides a variable chemical stock for diagenetic fluids to interact with (i.e., dolomitization, cementation).

Collectively, the imposition of burrows at the sediment–water interface perturbs the generally accepted geochemical zonations within (subaqueous) sediments, proffering a complex distribution of geochemical zones (Aller, 1980).

Summary

Microorganisms are integral to the chemical and physical changes sediment undergoes during the process of diagenesis. Through various chemoheterotrophic pathways, microorganisms are ultimately responsible for the

conversion of organic carbon to CO_2 (or CH_4) through the coupled reduction of dissolved (O_2 , NO_3^- , SO_4^{2-} , CO_2) or Fe(III)/Mn(IV) oxyhydroxides in the sediment. The inorganic by-products of chemoheterotrophy (HCO_3^- , Mn^{2+} , Fe^{2+} , NH_4^+ , NO_2^- , HS^- , HPO_4^{2-} , CH_4) are either transported from deeper sediment toward the seafloor, where residing chemolithoautotrophic bacteria use them as reactants in their metabolism, or their presence in pore waters may trigger secondary mineral precipitation and cement formation. Macrofauna also contribute to diagenetic reactions through their bioturbating activity. This includes the direct effects of burrowing and mixing of fresh sediment with older sediment, grazing and disintegration of intact organic remains, and the excretion of labile fecal pellets. Indirectly, they influence the solid-phase and pore water properties of sediment by increasing the transport of redox-active elements across the sediment–water interface.

Definition

Selenium, element 34, is a metalloid in row VIB of the periodic table. The main oxidation states are selenide (−2), elemental selenium (0), selenite (+4), and selenate (+6). Selenate and selenite are found in the oxic zone, while Se(0) is more abundant in the anoxic zone. Although hydrogen selenide may be produced by microorganisms, it is highly toxic. Se(−II) is more often found as organoselenium in the form of selenoproteins. The common methylated species (e.g., dimethylselenide, dimethyldiselenide) are volatile. Selenium can be a substitute for sulfur and is often found as metal selenide (e.g., Clausthalite, Crookesite). Selenium occurs in eight stable isotopes, the most common of which are Se80 (~50%) and Se78 (~24%), and nine radioactive isotopes.

The microbial oxidation of selenium is a slow process, whereas the dissimilatory reduction of selenate via selenite to Se(0) is rapid (Dowdle and Oremland, 1998). Selenate and selenite may also be methylated, and Se(0) can be further reduced to selenide (HSe^{−1}). Se(0) is insoluble, and bacteria form “nanospheres” of roughly uniform diameter (0.2–0.3 μm) (Oremland et al., 2004). These nanospheres can occur inside the cytoplasm or on the outside of the cell wall and may exhibit measurable isotope fractionation (⁸⁰Se/⁷⁶Se of −8.0‰ to −12.4‰) (Herbel et al., 2000). Selenium may be assimilated via the sulfur assimilation pathway.

Selenium is an essential element primarily needed for the synthesis of selenocysteine and selenomethionine (as reviewed in Stolz et al., 2006). Selenocysteine (Sec, U) is the 21st amino acid (encoded by UGA) and is found in a number of enzymes (e.g., glycine reductase, formate dehydrogenase). Sec requires four specific gene products: SelA, selenocysteine synthase; SelB, a special translation factor; SelC, a Sec-specific tRNA (tRNA^{Sec}); and SelD, the selenophosphate synthase. SelB recognizes the alternative coding of UGA for selenocysteine aided by a stem loop structure in the mRNA. The selenocysteine insertion sequence, or SECIS, is found within the 3′ untranslated region of the mRNA in archaea and eukaryotes and immediately downstream of the UGA codon in bacteria.

Over 20 species of selenate respiring prokaryotes are known and include members of the Crenarchaeota, low and high G + C Gram-positive bacteria, Halanaerobacter, and beta-, gamma-, and epsilon-proteobacteria; however, only a few species respire selenite. The respiratory selenate reductase (Ser) from *Thauera selenatis* is a heterotrimer (SerA, SerB, SerC) and belongs to the

DMSO reductase family of molybdenum enzymes. Two different methyltransferases have been identified. Bacterial thiopurine methyltransferase converts selenite and selenocysteine to dimethylselenide and dimethyldiselenide. MmtA (the calicheamicin-like methyltransferase) produces dimethylselenide and dimethyldiselenide from selenite and selenocysteine (as reviewed in Stolz et al., 2006).

SHALES

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

Historically, the term shale has been used to describe fine-grained sedimentary rocks of largely terrigenous derivation, dominated by mud-size particles (0.06 mm and smaller) and containing appreciable quantities (several 10%) of clay minerals. The definition of the term has been a subject of debate (Potter et al., 2005) because of the closely allied terms mud and clay for which competing definitions may emphasize grain size, mineralogy (clay dominated), or physical properties (plasticity). In place of shale, the term mudstone is also used widely and describes the same compositional spectrum of sedimentary rocks. Because shales span the clay–silt boundary, a good many rocks that are identified as siltstones in the literature also qualify as shales (and vice versa). Although the term shale traditionally had a “terrigenous” connotation, shales that accumulated in sediment starved settings may to more than 50% consist of microbially induced early diagenetic cements (calcite, dolomite, ferroan carbonates, silica, authigenic clays, and iron sulfides), organic matter, and biogenic debris (fish bones, microfossils) upon close inspection. One could argue that the term “biogenic” would be more appropriate for these rocks.

Thus, categorizing shales is by no means a trivial exercise and the various classification schemes in existence (e.g., Ingram, 1953; Dunbar and Rodgers, 1957; Folk,

1965; Picard, 1971; Lewan, 1979; Blatt et al., 1980; Lundegard and Samuels, 1980; Potter et al., 1980; Stow and Piper, 1984; Macquaker and Adams, 2003) leave much to be desired. Many fine-grained sedimentary rocks contain variable amounts of a fine-grained carbonate component and it is common practice to use the terms shale and mudstone for rocks with less than 50% carbonate (Potter et al., 2005). Beyond that arbitrary cut-off the terms marl, micrite, limestone, and dolostone are most commonly used. The classification scheme proposed by Macquaker and Adams (2003), however, also includes fine-grained materials of non-terrigenous origin. The books by Potter et al. (1980, 2005) and Schieber et al. (1998) provide further information on this, as well as other topics concerning shales.

Fundamentally, shales span such a large compositional and textural spectrum that a comprehensive and meaningful classification will only be possible when we can build on a much larger body of case studies than currently available. At present it is probably pointless to agonize over the actual names given to shale types encountered in a given study. What matters primarily is that the rocks be dominantly fine grained, and that we report as accurately as possible their composition, texture, and fabric. The latter two are indispensable for meaningful descriptions of shales because they convey key insights into their transport and deposition (Schieber, 1999a; Schieber et al., 2007).

Significance of shales for geobiology

Although still understudied when compared to sandstones and carbonates (Schieber and Zimmerle, 1998), shales nonetheless are geologically important for multiple reasons. They constitute by volume two thirds of the sedimentary rock record and once examined systematically will contribute much to a better understanding of Earth history and the evolution of life. Because overall they accumulate slower than sandstones or carbonates, as much as 90% of geologic time recorded in sedimentary rocks may be preserved in shales.

Shales are an excellent matrix for fossil preservation, and contained fossils are comparatively easy to extract for study. Because their low permeability limits chemical exchange and access by oxygen, metastable skeletal minerals (e.g., aragonite) and even soft tissues may be preserved. It is not by accident that many of the world's most scientifically significant sites of fossil preservation (Fossil Lagerstätten; Seilacher et al., 1985) are found in shale successions. Notable examples are the Cambrian Burgess Shale (Morris, 1998), the Devonian Hunsrück Slate (Bartels et al., 1998), the Jurassic Posidonia Shale (Kauffman, 1978), and the Messel oil shale deposit (Wuttke, 1983). Preservation of fossils carries much valuable information, particularly in the case of marine shales. Fossils are useful because taphonomy (the study of organismal decay over time), spatial distribution of fossils, fossil diagenesis, morphological attributes of fossils

Shales, Figure 1 (a) TEM micrograph of modern mud from the continental slope off northern California at a burial depth of 5 cm. Illustrates the spatial relationships of a colony of bacteria (bc), its extracellular polymeric substances (ep), and the surrounding sediment matrix of clay (c) and organic matter (o). Scale bar represents 1 μm . (b) TEM micrograph of a modern mud from Eckernförde Bay, Germany. Shows the relationships between bacteria (b), their extracellular polymeric substances (ep), and the surrounding sediment matrix of clay (c), and organic matter (o). Scale bar represents 0.5 μm . (From Ransom et al., 1999.)

(e.g., reflecting adaptation to substrate conditions), fossil assemblages and comparison to modern counterparts, and paleocommunities (paleoecology) all can provide a wealth of information about the deposition of a shale succession (e.g., Allison, 1988; Brett and Allison, 1998).

Freshly deposited muds, the sediments destined to become shales after compaction, have an enormous internal surface area. Depending on the assumptions about particle geometry and water content, one can readily estimate that a liter of watery mud should have an internal surface area on the order of several hundred square meters (e.g., Fenchel, 1970). That is enough space to provide habitat for trillions (10^{12}) of microbial cells (Figure 1).

Deposition of shales

The sedimentology of shales has made progress over the past decades (Potter et al., 2005), and sedimentologists are gradually learning to appreciate the utility of the many small scale sedimentary structures observable in shales (e.g., Schieber, 1989, 1990a,b, 1999a; O'Brien and Slatt, 1990). When studied in polished slabs and petrographic thin sections, a wealth of information about depositional conditions and history can be gleaned from most shales (Figure 2).

Laminae are the most typically observed sedimentary feature in shales. They show a large range in thickness and lamination styles (even, discontinuous, lenticular, wrinkled etc.), and these may represent conditions that include quiet settling, sculpting of the sediment surface by bottom currents, and growth of microbial mats

Shales, Figure 2 Line drawing that summarizes features observed in a mudstone from the late Devonian Sonyea Group in New York. (From Schieber 1999a.) M = mica; Q = quartz; py = pyrite.

respectively (Schieber, 1986, 1999b). Internal lamina features, e.g., grading (a), random clay orientation (b), preferred clay orientation (c), sharp basal contacts (d), and sharp top contacts (e) may be interpreted as indicative of (a) event-sedimentation (e.g., floods, storms, turbidites), (b) flocculation or sediment trapping by microbial mats, (c) settling from dilute suspension, (d) current flow and erosion prior to deposition, and (e) current flow and erosion/reworking after deposition (Schieber, 1990a,b). Due to somewhat larger grain size, silt laminae are the most readily observed lamina type in shales and may imply

somewhat more energetic conditions. Examples are density currents (grading, fading ripples), storm reworking and transport (graded rhythmites), wave winnowing (fine even laminae with scoured bases), and bottom currents (silt layers with sharp bottom and top). Gradual compositional changes between, e.g., clay and silt dominated laminae are another commonly observed feature, and are suggestive of continuous (although slow) deposition, possibly from deltaic sediment plumes and shifting nepheloid flows.

For many years conventional wisdom has held that parallel laminae in shales are the result of settling from slow moving or still suspensions, and the common assumption was that this reflects distal deposition in comparatively deep water with only minor current activity. Recent flume experiments, however, have demonstrated conclusively that muds can be deposited from swift moving currents that are competent enough to move sand in bedload (Schieber et al., 2007). This occurs because muds have a strong tendency to flocculate, regardless of exact particle mineralogy and water composition. The floccules travel in bedload and form migrating ripples (Figure 3) that build up a contiguous mud bed if sediment supply is sufficient. In spite of accumulation via lateral accretion, after compaction these muds have a parallel laminated appearance, just like many shales in the rock record (Figure 4; Schieber et al., 2007). Obviously, it will be difficult from now on to ascribe a quiet, deep water setting to a laminated shale without corroborating evidence (e.g., paleoecology, trace fossils).

A variety of other small scale sedimentary features also occurs in shales, including mudcracks, load casts, flame structures, dewatering structures, graded rhythmites (Reineck and Singh, 1980), cross-lamination, loop structures (Cole and Picard, 1975), bioturbation (Wetzel and Uchmann, 1998), fossil concentrations and lags, all of

Shales, Figure 3 Migrating ripples of flocculated kaolinite in seawater, photographed through the bottom of a flume. Width of flume channel is 25 cm, flow direction indicated by red arrow. (From Schieber et al., 2007.) The ribbed “tails” behind the ripples are the eroded remains of foreset laminae.

which carry information about conditions of sedimentation. Among the more subtle sedimentary features are clay-filled mud cracks, brecciation due to desiccation, and sands or conglomerates that consist entirely of shale particles (Schieber, 1985). The latter can, for example, form as a result of soil erosion (pedogenic particles; Nanson et al., 1986; Rust and Nanson, 1989), erosion of cracked mud crusts, and submarine scouring of mud substrates by strong currents.

Biologic agents may produce microbial laminae and protection of mud surfaces from erosion (e.g., Schieber, 1986; O’Brien, 1990), or may manifest themselves as bioturbation and via destruction of primary fabrics (Wetzel and Uchmann, 1998). Infaunal activity that took place early in depositional history, when the muds had a high water content, may be exceedingly subtle and hard to detect after compaction (Schieber, 2003). In many instances of bioturbation sufficient proportions of primary features survive and can still be interpreted in terms of depositional processes. Careful examination of bioturbation features can provide additional information about substrate firmness, event deposits (escape traces), and rates of deposition. Fecal pellets and pelletal fabrics are another by-product of organic activity, and they are probably more abundant in mudstones and shales than commonly recognized (Pryor, 1975; Potter et al., 1980; Cuomo and Rhoads, 1987). Best seen in thin section, pellets typically differ from the shale matrix with respect to texture, color, and organic content. They range in size from 0.2–2 mm, are generally of elliptical outline, and

Shales, Figure 4 (a) Parallel-laminated black shale, New Albany Shale, Devonian, Indiana. Lighter laminae are silt enriched (the steeply inclined and slightly curved lines are saw marks). (b) A sample from the same core interval as seen in (a). In the center, we see inclined (to the left) truncated laminae, forming the outline of a compacted mud-dominated ripple. (c) Tracing of silt laminae visible in (b). Arrow marks an internal erosion surface. This is a fossil equivalent of migrating mud ripples observed in flume experiments. (From Schieber et al., 2007.)

flattened by compaction. If matrix and pellets are similar in composition and composed of particles of similar grain size, pellet identification can be challenging. Pellets of benthic versus planktonic organisms may be differentiated on the basis of composition (Cuomo and Bartholomew, 1991; Schieber, 1994).

Early diagenesis of shales

It is due to the abundance of endosedimentary microbes (Figure 1) that surficial muds are very active sediments from a geochemical perspective. Much of the initially buried organic material is remineralized in these water-rich sediments (80–90% initial water content), prompting the description of surficial muds as “fluidized bed reactors” (Aller, 1998). The microbial breakdown of buried organic matter requires terminal electron acceptors (oxidizing agents) and due to limitations by diffusion, overall abundance, and differences in energy yield for the various oxidation reactions, we observe a systematic exhaustion of available electron acceptors (e.g., oxygen, nitrate, iron (III), manganese (IV), sulfate, carbon dioxide) as we move downwards from the sediment-water interface. For these reasons closely comparable microbial decay profiles (Brett and Allison, 1998; Curtis et al., 2000) are observed in many marine sediments. For a detailed description of these microbial decay profiles, see Chapters *Sediment Diagenesis – Biologically Controlled* and *Pore Waters*.

A good number of diagenetic minerals, such as pyrite (Figure 5), are readily explained by these decay-reaction schemes (Brett and Allison, 1998; Curtis et al., 2000; Allison, 1988). For others that are not, associated pH shifts can nonetheless be instrumental for their precipitation. For example, early diagenetic silica (quartz) precipitation is not uncommon in shales (Figure 6). In Phanerozoic shales it is derived from the dissolution of biogenic opal (radiolarian, diatoms, sponge spicules) and fills pore spaces that range from tens of microns to as much as a millimeter in size (Figure 7). Quite frequently these pore fills (in situ quartz) are mistaken for detrital quartz (Schieber, 1996; Schieber et al., 2000).

If phosphorous is abundant in the initial mud, such as due to accumulation of phosphatic skeletal material, phosphatic concretions, ranging in size from less than a mm to more than 100 mm's, may form (Figure 8). An early diagenetic phosphate matrix seems to be an excellent medium for preserving minute details of soft tissues, such as in the Neoproterozoic Doushantuo Formation of China (Shen et al., 2000).

Due to the rapid and systematic expulsion of pore waters and decrease of porosity during compaction, early diagenetic minerals in shales are preferentially preserved. For this reason, shales contain a rich record of geochemical processes that relate closely to the chemistry of the overlying ocean waters and paleoceanographic conditions. When studied systematically, the authigenic component of shales holds the promise to capture a snapshot of seawater and/or porewater chemistry. With the necessary

Shales, Figure 5 Pyrite framboid from bottom muds of the Santa Barbara Basin. Note regular arrangement of euhedral subcrystals. The sediment layer in which this framboid occurs is only a few years old. Pyrite formation is associated with the activity of anaerobic bacteria that utilize seawater sulfate (SO_4) as an oxygen source and generate hydrogen sulfide as a byproduct. They are among the most common and familiar of early diagenetic mineral formations in shales.

age constraints, this may enable us to develop a much more detailed record of ocean geochemical changes than currently available.

Conclusion

Shales result from the complex interplay of a range of geologic variables and processes, and there are no easy answers and no “one size fits all” models. Although these rocks have an (undeserved) reputation for being drab, uniform, and uninteresting, the repay the investigative challenges they pose by being a rich storehouse of information about the geologic past. Sedimentological study includes recognition and tracing of facies changes, sedimentary features, shale fabrics, erosion surfaces and internal stratigraphy, as well as information that can be derived from interbedded non-shale lithologies. Paleontological studies may provide data on paleo-oxygenation, primary production, substrate conditions, paleocurrents, bathymetry, and paleosalinity (Schieber et al., 1998). Petrographic investigations provide the basic inventory of shale constituents, and may yield clues about provenance, compaction history, chemical conditions, sedimentary processes (via small scale sedimentary structures), and the origin and maturation of organic matter (Taylor et al., 1998). Chemical analysis of major and trace elements can provide information on provenance (Roser and Korsch, 1986), and a range of proxies for paleo-oxygenation (Jones and Manning, 1994). Organic geochemistry can furnish information on the source of organic matter, its dispersal,

Shales, Figure 6 SEM photomicrograph (backscatter image) of a pore space in the Devonian New Albany Shale (Indiana, USA), illustrating suboxic to anoxic diagenesis. Light gray mineral **an** is ankerite (Fe-Mg-Ca-carbonate) that initially grew in the interior of a *Tasmanites* cyst (dark black line), a locally reducing and anoxic microenvironment. Very early growth is indicated by the uncompacted *Tasmanites* wall and the overall circular growth of carbonate (**an** + **mc**) cement. Outside of the protected microenvironment of the cyst we see growth of manganoan calcite (**mc**, darker gray), indicating suboxic conditions in the sediment and oxygenated bottom waters. (From Calvert et al., 1996.) The carbonate cement is surrounded by fine crystalline quartz (**qu**), derived from dissolution of radiolarian opal. (From Schieber et al., 2000). The image suggests that pore waters were initially alkaline, allowing for precipitation of carbonates and dissolution of biogenic opal, and that this was followed by a lowering of pH that led to precipitation of quartz. This image illustrates the level of insight one can derive from careful petrographic study of early diagenetic cements.

and maturation (Engel and Macko, 1993). Certain organic molecules, such as photosynthetic pigments, may survive as “carbon skeletons” (biomarkers), and may identify the original source of diagenetically altered organic matter and potential indicators of water column anoxia (Brassell, 1992).

Fundamentally, shales do not give up their secrets easily. The tools are at hand, however, to extract a wide range of data from them and allow for multiple avenues of inquiry (Schieber et al., 1998). Interpretations that rely on just one perspective (e.g., petrography, fabric study, trace element geochemistry, or organic geochemistry) typically do not match conclusions derived from a different line of inquiry. Shales need to be investigated in a multidisciplinary way and at multiple scales because of the complex interplay of variables that produces them. Conclusions derived from microscopic features must be in agreement with insights coming out of basin scale studies, as well as with findings from all scales in between.

Shales, Figure 7 Authigenic quartz (chalcedony) in the late Devonian Chattanooga Shale (Kentucky, USA). (a) Photomicrograph in transmitted light. The clear/bright grains are chalcedonic infills of algal cysts (*Tasmanites*). (b) SEM image (backscatter) from the same specimen, showing more clearly the rounded-lobate outlines of the quartz grains and the enclosing cyst walls (black rim). For a detailed discussion of these features see Schieber (1996) and Schieber et al. (2000).

Shales, Figure 8 SEM photomicrograph (backscatter image) of an example of early diagenetic phosphate precipitation. The image shows what appears to be a colony of phosphate encrusted bacteria (Mid-Proterozoic Bijaigarh Shale, India).

Classification

Bacteria – Proteobacteria – Gammaproteobacteria – Alteromonadales – Shewanellaceae (Ivanova et al., 2004), fam. nov. – *Shewanella* (MacDonell and Colwell, 1985), gen. nov.

Definition

Assumed as one of the first metabolic processes of ancient microbial life (prior to oxygen, nitrate, and sulfate respiration), microbial iron reduction is still of particular interest

in recent geobiological systems. The efficiency of iron reducing microorganisms in utilizing structural or crystalline solid-phase Fe^{3+} oxide minerals as electron acceptors with respect to nutrient availability and pH is still matter of discussion; this type of metabolism, however, is an ubiquitous phenomenon, applied by a wide range of species throughout the Archaea and Bacteria (Weber et al., 2006 and references therein). Members of the family *Geobacteraceae* and the genus *Shewanella* are among the most significant and common studied organisms with regard to dissimilatory iron reduction and oxidation of organic matter in soils, sediments, and groundwater.

According to the surface complexation model (Dzombak and Morel, 1990), Warren and Ferris (1998) report on an equilibrium between ferric iron sorption and precipitation reactions on bacterial surfaces, emphasizing iron-reducing bacteria like *Shewanella* as highly reactive key players in pristine and contaminated waters (Pedersen and Albinsson, 1991).

Actually including 50 recognized species (List of prokaryotic names with standing in nomenclature: <http://www.bacterio.cict.fr/>), the genus *Shewanella* features Gram-negative, facultatively anaerobic, dissimilatory metal-reducing, rod-shaped organisms. Due to their highly diverse physiology, they inhabit a wide range of redox-stratified environments varying in nutrient composition, salinity, temperature, redox potential, and barometric pressure (marine and freshwater, surface, ground and deep waters, sediment, mud and soils), but also comprise symbiotic, epibiotic, and pathogenic species (Venkateswaran et al., 1998; Hau and Gralnick, 2007 and references therein). Under anaerobic conditions, most *Shewanella* species can produce hydrogen sulfide when grown on thiosulfate or polysulfide, and also can grow on lactate, pyruvate, formate, and on amino acids (Nealson and Scott, 2006 and references therein). For respiratory growth, they can use oxygen as well as a variety of different terminal electron acceptors, including nitrate, elemental sulfur, fumarate, dimethyl sulfoxide, and metals like Mn^{4+} , Fe^{3+} , As^{5+} , Cr^{6+} , Co^{3+} , Tc^{7+} , and U^{6+} (Nealson and Myers, 1992; Haas et al., 2001; Guha et al., 2003; Saltikov et al., 2003). As diffusion across the cell wall is not possible for metals in their solid form, metal-reducing *Shewanella* species specifically interact with the mineral surface to facilitate the electron transfer process by active cell adhesion in combination with a unique shuttle-system of proteins reaching from the cytoplasm to the outer membrane (Lower, 2001; Korenevsky and Beveridge, 2007; Fredrickson et al., 2008 and references therein).

Near-surface habitats may get limited in oxygen but not in minerals like iron oxyhydroxides (ferrihydrite, goethite, and hematite), in large part consisting of Fe^{3+} (Urrutia et al., 1998). In case of dissimilatory metal-reducing bacteria like *Shewanella*, Fe^{3+} is reductively dissolved during oxidation of carbon substrates, affecting processes like the biogeochemical cycle of iron and phosphorus, the oxidation of natural and anthropogenic carbon sources, and

biocorrosion. The respiratory reduction of metals turns these organisms to key players in groundwater ecology, as they contribute to the mobilization of occasionally harmful metals (e.g., arsenic) from the solid to the soluble phase (Malasarn et al., 2008).

SIDERITE

Volker Thiel
 University of Göttingen, Göttingen, Germany

Siderite is an iron carbonate mineral (FeCO_3 , 48% Fe) belonging to the calcite group (hexagonal crystal system). Magnesium and manganese may substitute for the iron. Siderite crystals are yellow to dark brown in color, rhombohedral in shape, and with curved and striated faces, and also occur in masses. Siderite is commonly found in bedded sedimentary iron ores, including banded iron formations (BIFs, see entry [Banded Iron Formations](#)), and in hydrothermal veins. It is also a common diagenetic mineral, forming at shallow burial depths in shales and sandstones where it tends to form concretions. The diagenetic formation of siderite strongly depends on the availability of Fe^{2+} ions in pore waters (see entry [Pore Waters](#)) and is thus a phenomenon of suboxic to anoxic environments (Berner, 1971). Diagenetic siderite precipitation has been linked to microbially mediated reactions, specifically to the release of ferrous (Fe^{2+}) iron due to dissimilatory iron reduction performed by Fe^{3+} -reducing prokaryotes (see entry [Fe\(III\)-Reducing Prokaryotes](#)) such as *Shewanella* (Roh et al., 2003; Hansel et al., 2003; see entry [Shewanella](#)). Microbially assisted siderite precipitation appears to preferentially occur in environments where the rate of bacterial iron reduction exceeds the rate of sulfate reduction performed by sulfate-reducing bacteria (Pye et al., 2006; see entry [Sulfate-Reducing Bacteria](#)). In sulfidogenic sediments, iron is largely precipitated as iron sulfide rather than as siderite (see entry [Iron Sulfide Formation](#)).

Definition

Siderophores are low molecular weight iron-specific organic ligands that are exuded by iron-limited organisms as part of a high-affinity iron acquisition strategy.

Introduction

Iron is a nutrient to almost all known organisms. Even though iron is the fourth most abundant element on earth, the acquisition of this nutrient poses a serious challenge to organisms in many natural environments. A particularly iron-depleted system is the photic zone of the marine water column (Kraemer et al., 2005). Here, soluble iron is removed by biological uptake and subsequent sinking of the biomass below the mixed zone. In ocean areas with particularly low iron concentrations relative to other nutrients in the photic zone, the primary productivity is limited by the low bioavailability of iron. This marine iron limitation may affect the global climate by limiting the efficiency of the marine carbon pump. However, even in soils that contain abundant iron-bearing mineral phases, iron acquisition poses a challenge to microbial and plant life. Indeed, the low solubility and dissolution rates of iron-bearing minerals in calcareous soils are responsible for large annual agricultural losses by plant iron limitation (iron chlorosis) (Kraemer et al., 2006).

The ability of organisms to scavenge iron from their surroundings is prerequisite to controlling intracellular iron concentrations within the physiologically required range (homeostasis). An efficient mechanism of iron

uptake involves the exudation of siderophores that are designed to bind iron(III) in the extracellular space with a sufficient affinity and specificity to ensure the formation of Fe(III)-siderophore complexes even in the presence of high concentrations of other competing cations and in the appropriate pH range. This high-affinity iron uptake strategy is used by bacteria (including cyanobacteria) in marine, freshwater, and terrestrial environments, by fungi and some plant species. Other iron acquisition mechanisms include the acidification of the environment, the reduction of Fe(III) coupled to Fe(II) uptake, or the secretion of other ligands (e.g., citrate) with lower affinity for iron. High-affinity iron uptake involving siderophores is generally the most efficient system in environments with extremely low iron availability.

Siderophore structure and properties

Siderophores are not defined by their chemical structure, but by their biological function. Several hundreds of distinct and structurally diverse siderophores are known. Siderophores are low molecular mass (<1,500 Dalton) organic ligands, typically chelating iron in hexadentate octahedral coordination, although siderophores with lower denticity are known. Iron is coordinated by hard ligating groups including hydroxamate, catecholate, carboxylate, and hydroxycarboxylate groups (Figure 1). The nature of the ligating groups and the optimization of the overall siderophore structure are responsible for their outstanding affinity for iron. For example, desferrioxamine B (DFO-B), a siderophore produced by the soil bacterium *Streptomyces pilosus* forms an iron complex with a 1:1 stability constant logK of 32.02 (Martell et al., 2001). The affinity of microbial siderophores for iron binding is much higher than for competing ions that are often found in high concentrations in the extracellular environment. For example, DFO-B does not, to measurable extent, coordinate with calcium in seawater or in pore water of calcareous soils (Kraemer et al., 2005, 2006). Most siderophores excreted by terrestrial organisms are highly water soluble, allowing the diffusion of siderophores toward insoluble iron sources. This is prerequisite to their function as an iron shuttle overcoming the necessity for the organisms to directly contact the iron source (Kraemer et al., 2006). However, amphiphilic siderophores possessing fatty acid tails have been isolated from cultures of distinct genera of marine bacteria (Martinez and Butler, 2007) and pathogenic bacteria. The inhibition of ligand diffusion away from individual bacteria by anchoring of amphiphilic siderophores in the plasma membrane seems to be advantageous in marine systems where bacterial abundances are low.

Graminaceous plant species, including agriculturally important crops, such as barley, wheat, and corn, are the only plant species known to possess a high-affinity iron uptake system. They exude a distinct class of iron-specific ligands with aminocarboxylate and hydroxycarboxylate functional groups, the so-called phytosiderophores or

Siderophores, Figure 1 Chemical structures of the phytosiderophore mugineic acid and of microbial siderophores desferrioxamine B (DFO-B) and aerobactin.

mugineic acids (Takagi, 1976; Takagi et al., 1984) (Figure 1).

Uptake of Fe(III)-siderophore complexes

Gram-negative bacteria bind siderophore complexes by a receptor in the outer membrane followed by shuttling to the cytoplasmic membrane. Gram-positive bacteria have a receptor anchored to the cytoplasmic membrane. The complexes are then delivered to the cytoplasm by a transmembrane protein (ABC-transporter) (Andrews et al., 2003). Similarly, graminaceous plants possess a high-affinity uptake system specific for iron(III)-phytosiderophore complexes (Curie et al., 2001). Some microorganisms are known to be endowed with uptake systems for iron complexes of siderophores that are not produced by the same organism.

The intracellular release of iron from internalized siderophores is promoted by either hydrolysis of the siderophore or reduction of ferric iron to ferrous iron followed by competitive sequestration of the iron (Miethke and Marahiel, 2007). The biosynthesis and exudation of siderophores as well as the expression of their uptake systems are highly regulated as a response to iron limitation (Hantke, 2001).

Siderophore concentrations in natural environments

The exudation of siderophores is a costly strategy in terms of cellular nutrient and energy budgets, particularly in systems with low bacterial densities such as oligotrophic marine systems (Völker and Wolf-Gladrow, 1999).

Therefore, it is not surprising that observed siderophore concentration in the environment do not exceed iron concentrations required for efficient uptake. Powell et al. (1980) have estimated hydroxamate siderophore concentrations in soil solutions to be between 10 and 100 nM. Essen et al. (2006) found up to 2 and 12 nM of the hydroxamate siderophores ferrichrome and ferricrocin, respectively, in soil solutions of podzolic forest soils. However, the quantitative analysis of siderophores in natural waters remains challenging due to their structural diversity and low concentrations. For example, siderophores have not been detected unambiguously in ocean water even though iron complexes with conditional stability constants comparable to siderophore complexes in the nanomolar and subnanomolar concentration range have been observed by voltammetric techniques (Rue and Bruland, 1995). Römheld (1991) has estimated that phytosiderophore concentrations in the rhizosphere can reach local concentrations of up to 1 mM in the soil solution.

Sources of iron

The soluble iron concentrations in oxic soils or surface waters are limited by the solubility of iron oxides, iron hydroxides, or hydrous ferric oxide. In the neutral to slightly alkaline pH range corresponding to the pH of calcareous soil solutions and ocean water, their solubility reaches a minimum below 1 nM (Liu and Millero, 2002). The presence of iron complexing organic ligands can increase the iron solubility. Thus, iron complexes with low molecular weight organic ligands, fulvic and humic acids, as well as iron-bearing mineral phases (including

primary silicates and pedogenic iron oxides) are the most important iron sources for high-affinity uptake systems (Kraemer, 2004). Prerequisite for iron sequestration from these sources are the superior affinity of siderophores for iron compared to the stability of the iron complexes or minerals that serve as iron source and reasonably fast rates of the associated ligand exchange or dissolution reactions.

Siderophore promoted dissolution of iron oxides and iron-bearing silicates

Siderophores promote iron sequestration from iron oxides (Kraemer et al., 1999) and iron-bearing primary (e.g., hornblende [Liermann et al., 2000]) and secondary silicates [e.g., kaolinite (Rosenberg and Maurice, 2003)]. The effect of siderophores on iron dissolution rests on their ability to increase the solubility of iron and to accelerate dissolution rates. It has been shown that bacterial and plant siderophores promote iron oxide dissolution in the dark by a ligand-controlled dissolution mechanism, where the rate of dissolution is a linear function of the adsorbed siderophore concentration (Kraemer et al., 1999; Reichard et al., 2005). This mechanism is important in high-affinity iron acquisition by graminaceous plants. Considering the low concentrations of microbial siderophores observed in natural systems, their main function seems to be to increase solubility of iron oxides, generating thermodynamic driving force for other dissolution mechanisms (Cheah et al., 2003; Reichard et al., 2007).

Photochemistry of siderophore complexes

Soluble iron complexes of siderophores possessing α -hydroxycarboxylate ligating groups photolyze in seawater under irradiation by sunlight, resulting in oxidation of the ligand and formation of transient Fe(II) that is rapidly reoxidized (Barbeau, 2006). Both the Fe(II) and iron bound to the oxidized ligand are bioavailable to phototrophic phytoplankton that cannot take up Fe(III)-siderophore complexes. Moreover, siderophores promote photoreductive dissolution processes that tend to be faster than ligand-promoted dissolution reactions (Borer et al., 2005). These photochemical processes may be of key importance for algal and bacterial iron acquisition in marine systems.

Formation of siderophore complexes with other metals and their uptake

A prerequisite for the efficiency of the high-affinity iron uptake system is the ability of organisms to discriminate against uptake of other (potentially deleterious) metal ions. The selectivity of the uptake system is ensured by the high specificity of siderophores for iron binding relative to most cations in solution and by the specific recognition of iron(III)-siderophore complexes by receptors at the cell surfaces. However, some exceptions to the selectivity of iron binding and uptake are known. Siderophores have a high affinity for metal ions with an equal or higher charge to radius ratio than Fe(III). For example, the

siderophore DFO-B forms a Pu(IV) complex with a 1:1 stability constant that is orders of magnitude higher than the corresponding iron complex (Boukhalfa et al., 2007). Moreover, slow uptake of Pu(IV)-siderophore complexes by the high-affinity iron uptake system of *Microbacterium flavescens* has been observed (John et al., 2001). The formation of plutonium-siderophore complexes and their bacterial uptake illustrate that the selectivity for a metal ion other than iron does not necessarily imply that the metal ion is actively targeted by the high-affinity uptake system for the purpose of nutrition. Also, the siderophore DFO-B has a high selectivity for the trivalent manganese ion (Duckworth and Sposito, 2005). Manganese in this redox state is not commonly observed in the absence of the siderophores, but the shifted redox potential of the complex stabilizes Mn(III) under conditions that are found in natural systems. In order to appreciate the effect that siderophores may have on the geochemistry of metal ions other than iron, it is important to keep in mind the extremely low siderophore concentrations measured in natural systems (vide supra).

Uptake of phytosiderophore complexes of Fe(II), Ni(II), Zn(II), Cu(II), Mn(II), and Cd(II) by maize (*Zea mays*) has been observed (Schaaf et al., 2004), and it has been controversially discussed if their uptake by the high-affinity iron uptake system is regulated or fortuitous. A high-affinity uptake system also seems to promote the uptake of molybdenum and vanadium by the nitrogen fixing soil bacterium *Azotobacter vinelandii* (Bellenger et al., 2008). Methanotrophic bacteria use a high-affinity uptake system for copper acquisition involving the exudation of Cu(I) specific organic ligands, the so-called chalcophores. Chalcophores have a distinctly different architecture compared to siderophores involving nitrogen and sulfur as ligands (Kim et al., 2004).

Conclusions

The key role of siderophores in marine and terrestrial biological iron acquisition is well established. However, a thorough and quantitative understanding of their effect on processes involved in, e.g., global carbon cycling or crop production requires a better understanding of how siderophores influence the availability and distribution of iron among prokaryotic and eukaryotic organisms in complex ecosystems. New observations of siderophore photochemistry, their amphiphilic properties and their mineral surface chemistry as well as observations of iron speciation in natural systems are important steps in this direction. Furthermore, recent work has shown that nutrient acquisition involving the exudation of ion-specific ligands is not unique to high-affinity iron acquisition. Discoveries of other similar nutrient acquisition systems may reshape our thinking about the effect of trace metal biogeochemistry on the microbial ecology of oligotrophic natural systems and vice versa. Finally, the unique properties of siderophores and other ion-specific biogenic ligands continue to inspire technical applications in fields such as pollutant remediation or biomedicine.

SILICA BIOMINERALIZATION, SPONGES

Hermann Ehrlich

Dresden University of Technology, Dresden, Germany

Synonyms

Biosilicification, Silication

Definition

Biosilicification: The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges,

molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants.

Biom mineralization and biosilicification

Introduction

The growth in geobiology and biogeochemistry has led to a number of new existing research areas where the distinctions between the biological, chemical, and earth science disciplines melt away (Weiner and Dove, 2003). Of the intriguing topics that are receiving renewed attention, the study of biomineral formation based on organic templates is one of the most fascinating topics today. During the processes of biomineralization, the organic material acts variously as nucleator, cooperative modifier, and matrix or mold for the mineral ions with respect to biominerals formation which are characterized by a hierarchical order (Bäuerlein, 2007).

Biominerals may be deposited within the organism, and within its immediate surroundings or environment, as a result of the metabolism of the living creature (Skinner, 2005). The physiological pathways by which organisms precipitate skeletal minerals and the forms and functions of the skeletons they fashion have been shaped by natural selection through geologic time, and all have constrained continuing evolution in skeleton forming clades (Knoll, 2003). The variety of biomineralizers recently reviewed by Ehrlich et al. (2008a) can best be expressed by the fact that, approximately 128,000 species of molluscs, about 800 species of corals, 15,000 species of sponges including 550 species of glass sponges, 700 species of calcareous green, red and brown algae, more than 300 species of deep-sea benthic foraminifera, and 200,000 diatom species (Mann and Droop, 1996) exist.

Precipitation of silica on organic templates could have been abiotic, in which organic matter merely serves as a template for nucleation, or biogenic, i.e., induced by biological activities or a combination of both (Mukhopadhyay et al., 2004). Silicon, in the form of silicic acid, is a fundamental nutrient for diatoms, silicoflagellates, radiolaria, and many sponges, all of which polymerize it to build skeletons of biogenic silica (Maldonado et al., 2005).

Sponges

Sponges (Porifera) are the most simple and ancient multicellular animals on earth and live attached to the seabed or another substratum. Sponges diverged from other animals earlier in evolutionary history than any other known animal group, extant or extinct (Reitner and Mehl, 1996), with the first sponge-related record in earth history found in 1.8 billion year old sediments (Nichols and Wörheide, 2005). The huge diversity with respect to their natural habitat is probably the reason for the estimated number of approximately 15,000 different sponge species (Hooper and van Soest, 2002). To support life, sponges pump huge amounts of seawater (170–72,000 × their own body volume per day) through their bodies (Simpson,

1984) and filtrate it to capture food particles, such as bacteria, micro algae, other unicellular organisms, or dead organic particles. The whole sponge body is designed for efficient filtration of the surrounding seawater, which is essential because of the low nutrient availability at the sea floor.

The phylum Porifera (sponges) is divided into three classes, Hexactinellida and Demospongiae that comprise a siliceous skeleton and the Calcarea with a calcareous skeletal network (Bergquist, 1978). Significant separation of the Calcarea from the Hexactinellida/Demospongiae (Silicispongea) clade is also implied by fundamental differences in morphology and development: unlike Silicispongea, calcareans lack morphologically distinct microscleres, and their calcitic spicules are secreted intercellularly within an organic sheath (vs. formation of silica spicules onto an intracellularly secreted axial organic filament in Silicispongea (Botting and Butterfield, 2005)). Sponges bear only a few different cell types of which the sclerocytes produce the spicules, i.e., siliceous structures, which are often needle-shaped. These spicules often form a distinct skeleton, but occasionally they are loosely distributed throughout the sponge body without identifiable order or they are lacking entirely. Size, type, shape, combination of spicules, and their skeletal arrangements are the fundamentals of current sponge systematics (Erpenbeck et al., 2006; Boury-Esnault and Rutzler, 1997).

Among the siliceous sponges most important are the monophyletic class Hexactinellida, and the polyphyletic “Lithistida,” which includes taxa belonging to different groups within the class Demospongiae. Both classes are characterized by rigid skeletons of fused spicules.

Among the class Hexactinellida, the order Hexactinosida (subclass Hexasterophora) (Schulze, 1886), known since the late Devonian (Rigby et al., 1981, 2001), developed a rigid and, to a certain extent, firm skeleton that consists of fused hexactins. This fused, three-dimensional, generally right-angled skeletal network stays intact even after the death of the sponge.

Hexactinellida

Hexactinellida Schmidt (Porifera) are deep-water marine sponges defined by their production of siliceous spicules of hexactinic, triaxonic (cubic) symmetry, or shapes clearly derived from such forms by reduction of primary rays or terminal branches added to the ends of primary rays. They lack calcareous minerals and sclerified organic spongin as skeletal components. Siliceous spicules may be entirely loose, or partially fused to form a rigid basal and choanosomal framework. Their living tissues are mainly syncytial, with distinctive porous plugs joining differentiated regions of the syncytium to each other or to discrete cellular components. Flagellated-collar units are anucleate. Hexactinellids are viviparous and, from detailed study of a single species, produce distinctive trichimella larvae. Two subclasses are recognized by different microsclere forms – amphidiscs and hexasters.

Silica Biomineralization, Sponges, Figure 1 Specimens of glass sponge *Hyalonema (Corynonema) populiferum* Schulze, 1899 recently collected in Pacific (Oregon, USA) (a) possess high flexible anchoring siliceous spicules (b).

Hexactinellids include more than 500 described species, 7% of all Porifera, distributed in five orders, 17 families, and 118 genera (Schulze 1886, 1904; Sollas, 1888, Okada, 1928; Reischwig, 1971, 2002; Lévi et al., 1989; Mehl, 1992; Leys, 2003).

The taxonomy of the class Hexactinellida is very incomplete in the sense that probably not even half of its species are known to science. This is obvious from the fact that many of the hexactinellids species collected during recent deep-sea expeditions are new. The spicules of most hexactinellids are larger (Figure 1) and more luxuriously architected than those in demosponges (Tabachnick, 2002).

Demospongiae

In demosponges (Demospongiae Sollas, 1885) we have much the largest group, with 95% of all extant sponges. They are also the most diverse group. Some are freshwater but predominantly they are marine species living from the intertidal to the deepest seas, with around 15 orders, 88 families, and about 500 valid genera (Hooper and van Soest, 2002). The skeleton is composed of monaxononic or

tetragononic siliceous spicules (never triaxononic) bound together with collagen-like protein spongin in discrete fibers or loosely aggregated and ubiquitous collagenous filaments forming the ground substance of the intercellular matrix.

Because the morphology of the spicules differs species-specifically, they are used as a major taxonomic character. However, very little is known about the molecular mechanism(s) that determine the position and arrangement of the spicules within the demosponge skeleton (Uriz et al., 2003; Uriz, 2006).

Lithistid demosponges

Like hexactinellid sponges, lithistid sponges also contain siliceous skeletons comprising spicules. These spicules (desmas) interlock, rendering the skeleton rigid and often stony (Pisera, 2000, 2003; Kelly, 2000, 2003). At present little is known about the deposition of silica within this taxonomic order.

Lithistid sponges are commonly found on tropical and temperate seamounts and continental margins down to depths of about 1,000 m (Kelly, 2000). Several Southwest Pacific species, form large cups, bowls, and plates that extend linearly from the sponge margin. Close inspection of the lamellae show irregular or concentric ridges, indicating that silica deposition is not continuous but rather variable in nature (Ellwood et al., 2007) presented detailed records of trace metals and carbon isotopes to understand siliceous spicule formation in the deep-sea lithistid sponge *Corallistes undulatus* Lévi and Lévi, 1983 (Demospongiae: Corallistidae). X-ray analysis of two longitudinal sections removed from the lamellae of the cup-shaped sponge revealed 144 and 137 light and dark density band-pairs, respectively, within the siliceous skeleton. Although there was some variability in the ^{32}Si data, the overall age established using these data indicated that the sponge was between 135- and 160-year old.

Forms of the silica deposition in sponges

Spicules, skeletal frameworks and desmas are the main forms of the silica deposition in sponges as shown in Figure 2.

The history of the discoveries related to sponge spicules is well reviewed by Vosmaer and Wijsman (1905). According to these authors, after Schweigger in 1819 had demonstrated that the spicules of sponges in some cases do not consist of calcium carbonate, Grant in 1826 found them to contain silica, and Bowerbank in 1841 showed that, in addition to the silica some organic matter is present. Sollas in 1885 likewise finds that the sponge silica resembles opal. He states in general that the refractive index of sponge silica is that of opal or colloidal silica, and not of quartz. This kind of opal was proposed by Vosmaer and Wijsman to call *spicopal*, however, the organic matter of the spicule was called by F.E. Schulze *spiculine*. As to the structure of the spicules, Gray in 1835 had found them in *Hyalonema* glass sponge to

Silica Biomineralization, Sponges, Figure 2 SEM images of three main forms of the silica deposition in sponges: (a) spicules of demosponge *Suberites domuncula*; (b) skeletal silica-chitin-based framework of *Farrea occa* glass sponge (both images courtesy C. Ekkert), (c) siliceous desmas of *Neopelta* sp. lithistid demosponge. (Image courtesy A. Pisera.)

consist of layers, which became conspicuous by heating. These layers concentrically surround a “central canal,” which is filled out, as Kölliker in 1864 has shown, by an organic mass, the axial rod. Claus in 1868 found that the

Silica Biomineralization, Sponges, Silica Biomineralization, Sponges, Figure 3 SEM images of the axial rod (axial filament) of demosponge *S. domuncula* (a) show interconnections between individual proteinaceous nanofibrils (b) visible only at high magnification.

silica which directly surrounds this central rod, is homogenous. He called this homogenous cylinder the axial cylinder. The sponge spicule thus consists of a central organic axis, surrounded by concentric layers of opal, the outermost of which is invested in a spicule sheath of organic matter or rather of organic matter in intimate association with silica (Vosmaer and Wijsman, 1905) (Figure 3).

Using the freshwater sponge *Ephydatia fluviatilis*, Weissenfels and Landschoff (1977) and Weissenfels (1989) demonstrated that the formation of spicules starts in sclerocytes within a specific vesicle. After the production of an axial organic filament, silicon is deposited around it and the whole process of forming a spicule (190 µm in length and 6–8 µm in diameter) is completed after 40 h, at 21°C.

Siliceous sponge spicules have traditionally been separated into two categories termed, according to their size, megascleres and microscleres (Lévi, 1973). They are highly diverse in sponges and the selection pressures responsible are difficult to envisage. There are over 12 basic types of megasclere and 25 types of microsclere reported in Demospongiae, 20 basic types of megasclere, and 24 types of microsclere in

Hexactinellida, besides a long list of variations of the basic types (Lévi, 1973, 1993; Garrone et al., 1981; Simpson 1984, 1990; De Vos et al., 1991; Bavestrello et al., 1993; Boury-Esnault and Rutzler, 1997; Tabachnick and Reiswig, 2002).

Desmas differ from typical demosponge spicules: first they are joined by articulation; second, they always display irregularity and often complex morphology and sculpture. The most basic difference, perhaps, is in the fact that the crepis or axial filament is usually very short (or even invisible) and extends only a short distance from the spicule center. Growth ceases very rapidly, and an important part of a desma, including secondary branches as well as elements of sculptures, does not depend on the axial filament (Sollas, 1888; Lévi, 1991).

In contrast to the high diversity of spicules, there are relatively few basic types of skeletal framework in demosponges. Six elemental types of skeletons with intermediate forms can be differentiated: hymedesmoid, plumose, axial, radiate, reticulate, and arranged in strength confusion (Boury-Esnault and Rutzler, 1997)

Chemistry of sponge silica

It is established that siliceous sponge spicules of both the Hexactinellida and Demospongiae consist of hydrated amorphous silica (Simpson, 1989; Uriz et al., 2003; Uriz, 2003, 2006). Chemically, they differ only slightly in their $\text{SiO}_2\text{:H}_2\text{O}$ proportions. Desma bearing demosponges ("Lithistida") have a ratio of 5:1 whereas Hexactinellida have 4:1 (Hartman, 1981). Holzhüter et al. (2005) reported that spicules of demosponge *Suberites domuncula* consist of more than 90% silicon and oxygen. They found that at the molecular level silica of sponge spicules has following amorphous structure: SiO_4 tetrahedra are connected to form polyhedra, which are comparable with those found in silica gels. These polyhedra form silica particles up to 3 nm in size which are interconnected forming a dense packing containing pores. However, recently Mugnaioli et al. (2009) reported for the first time crystalline nanorod-like structures which were localized within the organic axial filament of the primordial spicules of demosponge *S. domuncula*. These nanorods have a layered structure that matches smectitic phyllosilicates. It was suggested that this kind of crystalline structure acts as an inorganic template and gives shape and orientation to the newly forming spicule, although its function is admittedly not yet fully understood.

The major trace elements found in the spicules and siliceous sponge skeletons (i.e., S, Ca, K, Na, and Cl) are also the most common in seawater (Sandford, 2003). It was suggested (Aizenberg et al., 2004) that sodium can play an important role in physicochemical properties of glass sponge spicular formations (Figure 4).

Mechanisms of silicification in sponges

Silica deposition is a fundamental process in sponges. According to the modern point of view, two different

Silica Biomineralization, Sponges, Figure 4 SEM image and EDX carbon map (a) of microtome-cut spicule of *Euplectella aspergillum* glass sponge cross section highlights the presence of an organic filament. (b) EDX Na map indicates an enhanced concentration of Na ions within the spicule cross section, with the highest density of Na occurring in the 2- μm core. (Images courtesy J. Aizenberg.)

mechanisms of silicification in sponges are proposed: enzymatic (silicatein-based) and nonenzymatic, or self-assembling (chitin- and collagen-based).

Silicatein-based silicification

The group of Morse (Shimizu et al., 1998; Cha et al., 1999; Shimizu and Morse, 2000; Weaver and Morse, 2003; Weaver et al., 2003) discovered that organic filament in demosponge *Tethya aurantium* is composed of a cathepsin L related enzyme, termed silicatein. They cloned two of the proposed three isoforms of silicateins, the α - and β -forms, from this demosponge (Cha et al., 1999). In subsequent years these molecules were cloned also from other sponges, among them *S. domuncula* and *Lubomirskia baicalensis* (as reviewed in Müller, 2003; Müller et al., 2007). The spicules are produced in special cells, the sclerocytes; that formation starts intracellularly around a silicatein filament and is completed extracellularly by apposition of silicatein onto the growing spicules (Müller et al., 2005, 2006). Cathepsin L is an endopeptidase which cleaves peptide bonds with hydrophobic amino acid residues in P2 and P3 positions and occurs in lysosomes as well as extracellularly as secreted enzymes. The silicateins are distinguished from the cathepsins by the replacement of the first amino acid residue in the catalytic triad, cysteine by serine (Shimizu et al., 1998). It has been proposed that serine increases the nucleophilicity during the nucleophilic attack at the silicon atom. The polymerization-promoting activity of the silicateins has been shown to be catalytic and not stoichiometric. It is possible that the controlled punctuated secretion of low

Silica Biomineralization, Sponges, Figure 5 The chemical mechanism proposed by Fairhead et al. (2008) to operate for the polymerization of silicic acid using silicatein molecules. The authors proposed H163 deprotonates Si(OH)_4 ; the extensive water network could permit proton shuttling. They illustrated one possibility.

concentrations of monomeric silicateins, pulses in the transitory flux of silica-precursor molecules, oscillations in the pH, ionic, or other conditions of the condensation environment, or a combination of these factors may be responsible for the annular patterning and continued deposition of silica in spicule biosynthesis in vivo once the axial filament has become completely covered during the early stages of silica deposition around this proteinaceous core. Alternatively, the continued growth of silica may be a result of dangling bonds at the growth surface of the newly deposited silica (Saito et al., 1995).

There are two possible mechanisms for enzyme catalysis (Fairhead et al., 2008): (1) stabilize at the active site one molecule of deprotonated silicic acid (the nucleophile) which will then react with another molecule of silicic acid; or (2) stabilize a protonated silicic acid (the electrophile) which will then react with another molecule of silicic acid. In proposed mechanism (Figure 5) (Fairhead et al., 2008), the roles of C25S location and flanking mutations are simply to create a sufficiently sized pocket that will allow recognition of the tetrahedral Si(OH)_4 molecule in such a way that H163 location can deprotonate it. The deprotonated Si(OH)_4 protein complex can be thought of as a template for condensation reaction. In this proposal, there is no need to involve a high energy covalent intermediate. The presence of a specific Si(OH)_4 transporter in sponge suggests the true substrate in vivo is indeed silicic acid, not high energy silicon alkoxides. This being so, the simple acid–base activation mechanism proposed by authors seems a good model for the biological process.

According to Müller et al., formation of spicules is a biologically controlled extracellular process (Schröder et al., 2006; Müller et al., 2007). The following model of silicification in demosponges is derived from observations and propositions put forth by Morse's and Müller's groups (reviewed in Leys et al., 2007). Sclerocytes secrete axial filaments composed mainly of silicateins but other organic

molecules are included. Silicatein acts as a structural template for formation of the highly organized mesoporous axial filament. Silicate is used or is actively taken up into the sclerocyte and complexed with specific proteins to form an as yet unidentified organic-silica substrate. The organo-silica complex is transported across silicalemma to the "silica deposition space." Silica from organo-silica substrate is polymerized on the outer surface of the mesoporous axial filaments as nanospheres, perhaps at serine and histidine catalytic centre sites, and the complexing protein is released and possibly recycled to the sclerocyte cytoplasm.

Growth of the axial filament continues at spicule tips, providing primary patterning of the spicule, while at the same time transport and deposition of silica continue on lateral spicule surfaces between the tips. Once the first few layers of silica nanospheres encase the axial filament, enzymatic activity can no longer be expressed by silicateins of the axial filament. Continuing deposition of silica on the outer surface of spicules is facilitated and controlled by silicatein at active sites on the silicalemma, resulting in production of specific patterned morphologies of spicules. Several elements of this model remain unverified. Other unknowns include the roles of the minor non-silicatein organic compounds incorporated in axial filaments, whether silicateins associated with the silicalemma are the same forms as those in the axial filaments and how the final high-fidelity submicroscopic external patterning on spicule surfaces is genetically controlled. However, recently Kozhemyako et al. (2009) identified silicatein genes (*AcSilA* and *AcSilB*) in nonspicule-forming marine sponge *Acanthodendrilla* spp. The authors suggest that silicateins could participate also in the functions unrelated to spiculogenesis.

Chitin- and collagen-based silicification

Aminopolysaccharide chitin has a nanofibrous structure and the chain of pyranose ring arranges almost parallel to the (100) plane and extends along the fiber axis (Iijima and Moriwaki, 1990). The chitin molecule has C=O, O–H, and N–H groups and oxygen atoms, which have affinity to the calcium, phosphate, carbonate, and hydroxyl ions of corresponding calcium phases. However, the same functional groups possess affinity to silicate ions. Because there is a possibility that such an oriented organic matrix acts as a template, or an ordered structural framework, it was hypothesized the existence of naturally occurring silica-chitin composites (Ehrlich et al., 2007). Moreover, silicon was found associated with glycosaminoglycans bound as an ether or ester-like silicate with C–O–Si or C–O–Si–O–Si–O–C bonds, in amounts of one Si atom/130–280 repeating units of the organic (Schwartz, 1973). The role of chitin in biosilicification is still not completely understood. Although chitin is one of the most important biopolymers in nature, knowledge of its interaction with silicon in vivo was absent up to now. Only recently, Ehrlich et al., isolated and identified

chitin from skeletal formations of some marine glass sponges for the first time. The presence of chitin within the framework skeleton of *Farrea occa* (Ehrlich et al., 2007) and *Euplectella aspergillum* (Ehrlich and Worch, 2007a) as well as separate spicules *Rossella fibulata* (Ehrlich et al., 2008c) could also be revealed by gentle NaOH-based desilicification technique established by Ehrlich et al. (2006) and Ehrlich and Worch, (2007b). The structure of the chitin extracted from these sponges turned out to be similar to alpha-chitin from invertebrates.

It was suggested that silicate ions and silica oligomers preferentially interact with glycopyranose rings exposed at the chitin surface, presumably by polar and H-bonding interactions (Ehrlich et al., 2008b). On the basis of the obtained results, authors proposed a model for the nanostructure of the naturally occurring silica-chitin composite unit, including interaction between poly-N-acetylglucosamine fragment of the chitin nanofibril and silica nanoparticles, which can be seen in Figure 6.

Because chitin could play a crucial role also in biosilicification in fungi (Kolb et al., 2004), it was hypothesized (Ehrlich et al., 2007) that chitin molecules are probably part of a very old organic template system involved in a biosilicification phenomenon, which was established a long time before the origin of first metazoan (e.g., glass sponges).

Recently, Ehrlich et al. reported for the first time on example of *Hyalonema sieboldi* glass sponge that its spicules are a biocomposite containing a silicified collagen matrix, and that high collagen content is the origin of the unique mechanical flexibility of the spicules (Ehrlich et al., 2006; Ehrlich and Worch, 2007b). Especially, interest is paid now to newly discovered highly hydroxylated collagen isolated from *H. sieboldi* spicules (Prof. M. Collins personal communication). Glass sponges are largely restricted to deep, cold-water (between 0 and 4°C) habitats (Tabachnick, 1991; Janussen et al., 2004; Dohrmann et al., 2008). Therefore, from the ecological point of view collagen- (as well as chitin-) based silicification which occurs in spicules and other skeletal formations of these sponges is an example of unique cold-water biomineralization. There is no evidence in the literature about silicatein activities at this temperature level. Skeletal biomineralization requires energy and so imposes a metabolic cost on skeleton-forming organisms (Knoll, 2003). The hypothesis is that probably some phosphate moieties and ATPase-based mechanisms are in some way involved in biosilicification at temperatures near zero (Ehrlich, 2009).

The procedure of alkali slow etching opens the possibility to observe the forms of collagen fibrils located within silica layers of sponge spicules and their distribution. For example, the results obtained by SEM observations of the desilicified spicular layers of *Monorhaphis chuni* provide strong evidence that collagen fibrils' orientation within spicules possesses twisted plywood architecture (Ehrlich et al., 2008b). Typical fibrillar formations were observed within the tubular silica structures of this sponge in all layers starting from the inner axial channel

containing axial filament (Figure 7c) up to the outermost surface layer of the spicules as shown in Figure 7b and Figure 7d. The fibrils in each cylinder form individual concentric 2D networks with the curvature of the corresponding silicate layers. These layers of about 1 µm in thickness are connected among each other by protein fibers (Figure 7a), which possess a characteristic nanofibrillar organization. Partially desilicified nanofibrillar organic matrix observed on the surface of silica-based inner layers of the demineralized spicule provides strong evidence that silica nanoparticles of diameter about 35 nm are localized on the surface of corresponding nanofibrils (Ehrlich et al., 2008b). This kind of silica nanodistribution is very similar to the silica distribution on the surface of collagen fibrils in the form of nanopearl necklets, firstly observed in the glass sponge *H. sieboldi* (Ehrlich et al., 2006; Ehrlich and Worch, 2007b). It was suggested that the nanomorphology of silica on proteinous structures described above could be determined as an example of biodirected epitaxial nanodistribution of the amorphous silica phase on oriented collagenous fibrillar templates (Ehrlich et al., 2008b). From this point of view, basal spicules of *Monorhaphis* sponges could be also defined as natural plywood-like silica-ceramics organized similarly to the crossed-lamellar layers of seashells. The authors suggested also that the matrix of the *M. chuni* anchoring spicule is silicified fibrillar collagen rather than collagen-containing silica which is the reason for their remarkable mechanical flexibility.

Biogeological aspects of silica deposition by sponges

Analysis of the biogeochemical cycle of silicon suggests that the biospheric environmental silicic acid concentration may have varied considerably during the time of life on Earth. Biochemical evolution today is proceeding within environments in which the silicic acid concentration is considerably lower than previous evolutionary periods (Exley, 1998).

Concomitant with the advent of dioxygen, about 2500 million years ago, and its subsequent gradual increase in atmospheric concentration from approximately 1% towards the level of 20% which is characteristic of today, there occurred an increasing number of organisms within which silicic acid was processed to silica. The most important of these, in the terms of their diversity, ubiquity (both freshwater and marine species) and biomass, were the diatoms, which occur however late in earth history (Mesozoic). The diatoms are characterized by a silica frustule which surrounds their cell wall. Interestingly that chitin-based organic networks are an integral part of cell wall biosilica from the diatom *Thalassiosira pseudonana* (Brunner et al., 2009). According to Maldonado et al. (2005), our current understanding of the silicon cycle in the ocean assumes that diatoms dominate not only the uptake of silicic acid, but also the production and

Silica Biomineralization, Sponges, Figure 6 Proposed model (adapted from Ehrlich et al., 2008c) of nanostructural organization of the naturally occurring silica-chitin composite unit (a) isolated from spicules of *Rossella fibulata* glass sponge. Silica nanoparticles tightly surround chitinous nanofibrils (b) Schematic view (c) shows a possible nanodistribution of silica on the surface of chitinous nanofibril. Image (d) represents the hypothetical scheme of interaction between silica and poly-N-acetylglucosamine-fragment of the chitin nanofibril and formation of the corresponding hydrogen bonds.

Silica Biomineralization, Sponges, Figure 7 Proposed model (c) of micro- and nanostructural organisation of the basal spicule of *Monorhaphis chuni* glass sponge with respect to organic matrix. Collagen nets, surrounding the spicules, showed a tight mat of nanofibrils (b, image courtesy C. Eckert). SEM image (a) shows a collagenous fibrillar matrix which could function as glue between concentric layers. Schematic image (c) represents the region of the axial canal and axial filament. The axial canal of *M. chuni* possesses a characteristic quadratic opening and contains oriented bundles of unsilicified collagenous nanofibrils. The base material of the walls of the axial canal and concentric layers distributed above it consists of silicified collagen fibrils with a twisted plywood orientation (d). This kind of fibrillar architecture could be responsible for the remarkable micromechanical properties of the spicule as a biocomposite made by silica and collagen.

recycling of biogenic silica, and that other organisms with siliceous skeletons, including sponges, radiolarians, and silicoflagellates, play a negligible role. The authors showed that the retention of Si by siliceous sponges in some sublittoral and bathyal environments is substantial and that sponge populations function as Si sinks. Therefore, sponges may affect Si cycling dynamics and Si availability for diatoms, particularly in Si-depleted environments. It was strongly suggested (Maldonado et al., 2005) that the role of sponges in the benthopelagic coupling of the Si cycle is significant. For example, Antarctic giant hexactinellids, such as *Rossella nuda* and *Scolymastra joubini*, which may be up to 2 m tall, 1.4 m in diameter, and up to 600 kg wet weight, containing up to 50 kg biogenic silica each (Maldonado et al., 2005). They are extremely slow-growing and seemingly reproduce only at long time intervals (Dayton et al., 1974) and become old, probably more than 1,500 years (Dayton, 1979; Gatti, 2002). While their living tissues represent only a modest biomass, the silicious spicules of hexactinellids become an important ecological factor. After the death of the sponges, the megascleres do not dissolve but accumulate on the bottom and over large areas to form spicule mats commonly about 50 cm thick but occasionally exceeding 2 m (Koltun, 1968; Dayton et al., 1974; Henrich et al., 1992). The mats structure the fauna living in and on them.

Marine sponges fractionate silicon isotopes during opal biomineralization to a greater degree than any other process on Earth thus far investigated (De La Rocha, 2003). This ability is in keeping with both their extremely negative silicon isotope composition and their inefficient uptake of silicic acid relative to other silicon-biomineralizing organisms.

Sponges seem to be important players in numerous geobiological processes (Reitner, 2004). For example, siliceous sponge reefs had a wide distribution in prehistoric times and once constructed the largest reefs known on earth, reaching an acme in the Upper Jurassic when a deep-water reef belt on the northern Tethys shelf existed that was 7,000-km long (Krautter et al., 2001). In present times hexactinellid sponges of the order Hexactinosida have constructed reefs at several localities off the coast of British Columbia, Canada. The reefs occur on relict glaciated seafloor areas with a low sedimentation rate and a high dissolved silica concentration in the Queen Charlotte Basin and in Georgia Basin (Conway et al., 2004, 2005) and the reefs represent stable communities that have been growing for up to 9,000 years. The main framebuilders include the hexactinosidan species *Aphrocallistes vastus*, *F. occa* and *Heterochone calyx* in Queen Charlotte Basin, and *A. vastus* and *H. calyx* in Georgia Basin (Conway et al., 2004). The framework of these reefs is constructed through several processes of framebuilding, and the reef matrix is derived from trapping of suspended sediments (Krautter et al., 2001). Similar framebuilding processes are thought to have contributed to the formation of the ancient reefs (Krautter

et al., 2006). Upwelling and downwelling oceanographic processes in a biologically productive coastal sea have contributed to the development of large reef complexes. The reefs form as bioherms (mounds) and biostromes (beds or sheets) that may rise up to 21 m above the seafloor and they cover around 1000 km² on the continental shelf. Individual reef complexes may cover areas of more than 300 km² and occur in 90–240 m depth range (Conway et al., 2001, 2005; Lehnert et al., 2005). Trapping fine-grained siliciclastic sediments in suspension in near-bottom currents is an important part of the mound-forming process, as it prevents the reef framework from collapsing under its own increasing weight.

Summary

Sponges are exclusively aquatic, sedentary, filter-feeding invertebrates, producing silica-made skeletons consisting of individualized elements (spicules) of lengths ranging from micrometers to centimeters, which can subsequently fuse or interlock with each other. The high diversity of spicule shapes and sizes in both fossil and living sponges has been repeatedly reported in literature. However, the mechanisms that determined such diversity remained elusive until recently. We are beginning to understand the mechanisms of spicule secretion and formation and the role of spicules and skeletal frameworks in the biogeology.

Molecular techniques and ecological experiments have demonstrated the genetic control of the process and the contribution of environmental factors to the expression of a sponge spicule, respectively. Silicatein proteins govern the enzymatic and structurally controlled synthesis of silica in marine demosponges. However, new biomineralization topics such as the role of chitin and/or collagen as self-assembling and nanofibrillar organized templates in sponge related biosilicification phenomena require further investigation.

SILICOFLAGELLATES

Silicoflagellates are planktonic, microscopic algae with siliceous skeletons, characterized by their simple geometries and remarkable variability. Taxonomically, they belong to different classes of the Stramenopiles and possess complex plastids derived from secondary endosymbiosis (see entry [Symbiosis](#)). Silicoflagellate skeletons may have considerable potential as environmental indicators and are common in fossil deposits, dating back to the middle Cretaceous (ca. 120 Ma), with species diversity reaching a peak in the Miocene (ca. 23–25 Ma). Today, only a single genus *Dictyocha* with approximately five recognized species exists. For more details, please refer to entry ["Algae \(Eukaryotic\)"](#).

SINTER

Robin W. Renaut¹, Brian Jones²
¹University of Saskatchewan, Saskatoon, SK, Canada
²University of Alberta, Edmonton, Alberta, Canada

Synonyms

Silica sinter; Siliceous sinter

Definition

Sinter: A sedimentary rock primarily composed of silica that is precipitated from hot waters at the vents of high-temperature (high-enthalpy) hot springs and geysers, and from cooled waters on their surrounding discharge aprons.

Geyserite. A dense, banded or laminated variety of sinter that forms at and near the vents of geysers and some high-temperature springs.

Some banded and laminated types of nonmarine carbonates (calcite or aragonite), including spring travertines and speleothems, have also been termed “sinter” or “calc-sinter.” We suggest that the geological term “sinter” should be restricted to *siliceous* deposits precipitated from silica-rich waters discharged at hot springs and geysers.

Introduction

Sinters are deposits of silica precipitated by hot waters discharged at the vents of hot springs and geysers. Most sinters are precipitated as noncrystalline opal-A, but they change to quartz during diagenesis. They form almost exclusively in high-enthalpy geothermal fields where the underground reservoir temperatures exceed $\sim 220^{\circ}\text{C}$, and so are most common in volcanic and tectonically active regions. Most geysers discharge from vents lined with sinter. Weed (1889) was among the first to discuss the role of microorganisms in the formation of sinter. After his pioneering work, very little scientific study was done on these rocks until Allen (1934) described sinters at Yellowstone. Walter (1976) undertook petrographic study of sinters, including stromatolitic types. Rimstidt and Cole (1983) made one of the first detailed studies of the chemistry of sinter formation. Krumbein and Werner (1983), followed later by Cady and Farmer (1996) and Jones and Renaut (1996), described, illustrated, and interpreted silicified microbes in recent sinters. Since then, interest in these unusual rocks has increased significantly, and more than 140 studies of sinters have been published during the past decade. The possible role of bacteria in silica precipitation has been a focus of much interest. Many filamentous and coccoid microbes preserved in recent sinters resemble the microfossils found in Precambrian quartzose cherts.

Morphology of sinter deposits

Most sinter is gray to white in color, but the addition of trace elements can produce vividly colored deposits such as the orange sinters found around the edge of Champagne Pool, Waiotapu, New Zealand (Jones and Renaut, 2003, Figure 2b). The main types of sinter deposit are *mounds*, which form around the vents of many geysers, *pool-rim dams* that precipitate around the margins of hot-spring pools, and various types of *terraces* and *platforms* that form downslope from the vent(s) on the spring or geyser discharge apron. Sinter mounds (Figure 1a) develop where aqueous silica precipitates from fluids that overflow the margins of a geyser vent or small-diameter point-sourced spring, or from silica that precipitates from air-borne spray. Sinter mounds can be columnar, domal, or broadly conical with slopes that range from nearly vertical to low angled ($<10^{\circ}$). Mounds vary from decimeters to meters in height and up to several meters in basal diameter. Many factors control mound morphology including the

original shape and dimensions of the vent, the volume and type of discharge (i.e., geyser versus hot spring activity), the original slope, climate (e.g., predominant wind direction), and water chemistry (e.g., silica concentration). Mound morphology can vary with time as the sinter deposits build up or the pattern or volume of discharge changes.

Pool-rim dams (Figure 1b) form where silica precipitates around the edges of hot-spring pools and some (fountain-type) geysers. The discharged water either flows across the lowest parts of the dam or escapes through erosional notches. Nested concentric pool-rim dams, each with different elevations, may form when mean water level in the pool changes because of external (e.g., hydrostatic) controls.

Water discharged from hot springs either flows across the land surface forming a “discharge apron” or it may flow directly into the local (nonthermal) drainage system. Outflow waters that mix with river or lake waters can be diluted below saturation with respect to amorphous silica, so that any sinter deposits are restricted to the vent area. If undiluted, however, the thermal outflow will cool progressively downslope leading to more silica precipitation. Sinter terraces (Figure 1c–f) commonly form where silica-laden waters flow across slopes, precipitating sheets of silica, as they cool and (or) evaporate. Each terrace is composed of a rimstone dam and pool. In scale, they range from miniterraces a few centimeters across, to large terraces tens of meters across, with dams several meters high. Some terrace pools temporarily pond water, but much of the outflow crosses terrace surfaces as largely unconfined sheets a few millimeters deep. Where several active vents lie near each other, their terraces may merge to form extensive flat sinter platforms.

Silica precipitated from hot waters also forms many small features including oncoids and pisoids (geyser eggs), which typically accrete in shallow pools near geyser vents; silica stalactites, which grow below overhanging terraces; and many small-scale ornate forms of geyserite on proximal sinter terraces (Figure 1e and g). Stromatolites develop locally in ponds or spring pools in the outflow system, usually where water temperature is $<70^{\circ}\text{C}$.

The thickest, most extensive sinter deposits form in neutral to alkaline waters (pH 7–9.5). The sinters that form in acid to neutral waters (pH 2–7) tend to be thin (millimeter to decimeter rather than meter thick). They lack some of the complex ornamentation of sinters forming in more alkaline fluids (Figure 1h), but commonly show spicular and bladed morphologies, and tend to be glassier in appearance than sinters forming in alkaline waters.

Microorganisms and sinter

Petrographic and scanning electron microscope (SEM) studies of sinter commonly reveal abundant silicified remains of microbes including coccoid and filamentous bacteria, eukaryotic algae, diatoms, fungi, and

(g) Ornate geyserite deposits near a geyser vent at El Tatio geothermal field, Chile. (h) Thin platy sinter precipitated by acidic waters on the southern shore of Hot Pools Lake, Rotokawa, New Zealand. The sinter, which was probably precipitated by capillary processes, shows desiccation(?) cracks partly filled by silica cements.

extracellular polymeric substances (EPS) (Figure 2). Near spring vents and on many terraces where waters have cooled to $<70^{\circ}\text{C}$, microbial mats commonly cover the substrate and can become encrusted and (or) replaced by opaline silica. Bunches of current-aligned, partially silicified, filamentous cyanobacteria (stringers) are present in some channels. If hydrothermal discharge is ephemeral and the terrace surfaces dry out periodically, microbial mats may be absent. However, biofilms, some thinly

(millimeter thick) coated by opaline silica, and endoliths may still be present either at or just below the terrace surface, including sites very close to active vents.

Microbial fossils are preserved in most settings from vent to distal discharge apron. In waters $>75^{\circ}\text{C}$, nonphotosynthetic prokaryotes, including heterotrophic and chemolithotrophic bacteria and archaea, are present, although their silicified remains are often difficult to identify. commonly inhabit waters from ~ 65 – 75°C (e.g., *Synechococcus*, *Chloroflexus*), with a wider range of cyanobacteria at temperatures $<65^{\circ}\text{C}$ (e.g., *Phormidium*, *Spirulina*, *Anabaena*, *Oscillatoria*, *Calothrix*, and others). Eukaryotic algae colonize substrates at temperatures $<60^{\circ}\text{C}$ and diatoms at $<45^{\circ}\text{C}$. Diatoms, fungi, and *Cyanidium* spp. are often the dominant fossil microbes in sinters precipitated from acidic fluids. Macrophytes, including grasses, wetland species, and trees and their root systems, may also be submerged by hot spring fluids and encrusted or replaced by amorphous silica.

Mineralogy and petrology

Most sinter is precipitated as noncrystalline opaline silica (opal-A: $\text{SiO}_2 \cdot n\text{H}_2\text{O}$) that can contain up to ~ 20 wt.% H_2O ; less commonly, chalcedony is a primary mineral. Although sinters precipitated from neutral and alkaline fluids are commonly monomineralic, silica precipitated from acidic fluids is commonly accompanied by kaolinite, ferric oxyhydroxides, alunite, jarosite, pyrite, and gypsum.

Sinters exhibit a wide range of textures and fabrics. Geyserites tend to be laminated, columnar, or stromatolitic, and generally have low primary porosity. Sintors that form distally from the vent are more diverse and include bedded and laminated facies that form on terraces, commonly with in situ silicified microbial mats, fenestral porosity, and intraclasts reworked from silicified mats upslope. Early cementation by opaline silica commonly masks the original fabrics, producing apparently massive sinter, but slight differences in the water content of the precipitated opal-A can help differentiate primary textures and cements (Jones and Renaut, 2004).

During diagenesis, the opal-A transforms to opal-CT, moganite, and ultimately quartz. The opal-A to opal-CT transformation can be rapid (Lynne et al., 2006; Jones and Renaut, 2007) and proceeds mainly by dissolution–reprecipitation reactions.

Origin of sinter

Silica solubility increases with increasing temperature, pH, and pressure, and can be influenced by other factors such as the presence of certain ions (e.g., Al, Fe) and salinity. Most silica precipitation at hot springs has been attributed to the cooling of thermal fluids that have equilibrated with respect to quartz, chalcedony, or volcanic glass at depth, and then rise rapidly to the surface, emerging as hot water supersaturated with respect to amorphous silica (White et al., 1956; Rimstidt and Cole, 1983; Fournier, 1985).

Much of the dissolved silica is present in its monomeric form (H_4SiO_4). As saturation increases, silica polymerization occurs through reactions that involve linear, cyclic, and three-dimensional forms of polymeric silica (Iler, 1979). In strongly supersaturated fluids, including some spring pools, nuclei grow by Ostwald ripening into nanospheres and microspheres (10 nm–1 μm) and may

form colloidal particle suspensions (sols). Continued growth of spheres can destabilize the sols and fine sediment settles from suspension. If the pH falls or the electrolyte concentrations increase (e.g., by evaporation), suspended particles may flocculate, forming aggregates that eventually sink to the substrate. In both cases, the silica sediment then undergoes cementation to form sinter. At sites of evaporative concentration, microspheres may coagulate to form gels. In contrast, at relatively low levels of supersaturation, dissolved silica precipitates mainly by heterogeneous nucleation upon existing substrates or suspended particles.

Evaporative concentration can induce silica precipitation at hot springs in semiarid and arid regions (e.g., Kenya Rift), although evaporation is usually less effective than cooling in humid environments. However, evaporation is an important mechanism on subaerial sites of periodic wetting including outflow terraces between geyser eruptions and sites receiving airborne spray. Seasonal freezing of geothermal outflow can also induce opal-A precipitation and agglomeration by “cryogelling,” which concentrates silica in residual fluid as ice is formed (Channing and Butler, 2007).

The pH and salinity also affect amorphous silica solubility. Nucleation and polymerization are inhibited in acidic waters because monomeric silica is slow to deprotonate (Fournier, 1985; Mountain et al., 2003), which explains the thin sinter development around acid hot springs. At $\text{pH} > \sim 9$, silica dissociates into other species, increasing the solubility. A rapid decrease in pH of a highly alkaline, silica-saturated thermal fluid might induce amorphous silica to precipitate on contact with neutral lake waters or groundwaters or if the fluid is acidified by microbes.

The waters that flow from most geysers and many hot springs in the geothermal fields of Iceland, New Zealand, Kamchatka, Chile, and Yellowstone, are strongly supersaturated with respect to amorphous silica so should precipitate silica abiotically upon rapid atmospheric cooling. Physical processes control the gross morphology of most sinter deposits, whereas chemical processes control the silica precipitation mechanisms. There has been much debate about whether or not microbes mediate silica precipitation and silicification, particularly in waters where homogeneous nucleation does not occur. Microbes can provide reactive surface ligands that adsorb aqueous silica from solution, and should therefore promote heterogeneous nucleation by reducing activation energy barriers. Three main mechanisms have been proposed: hydrogen bonding, cation bridging by metals (especially Fe), and electrostatic interactions (Phoenix et al., 2003; Lalonde et al., 2005; Konhauser, 2007, pp. 156–160). Although consensus has not yet been attained, most recent field studies (e.g., Jones et al., 2004) and laboratory experiments (e.g., Fein et al., 2002; Yee et al., 2003) suggest that the role of microbes in silica precipitation is largely incidental, especially in strongly supersaturated fluids. At lower levels of supersaturation, they may provide organic

substrates for heterogeneous nucleation. Bacteria (including cyanobacteria), however, control microfabric development in many types of sinter, over a wide range of scales and fluid temperatures (Jones and Renaut, 2003).

Fossil sinter

Fossil sinters, also termed paleosinters, are increasingly being recognized in the geological record. They commonly form “caprocks” to some epithermal mineral deposits (e.g., Guido et al., 2002) but are rarely a target of study. Two exceptions are the early Devonian Rhynie and Windyfield cherts of Aberdeenshire, Scotland (Trewin, 1994), and the Devonian–Carboniferous sinters of the Drummond Basin, Australia (Walter et al., 1996).

Conclusions

By mass, sinters are trivial compared to most sedimentary rocks, but their rarity belies their importance. Hot spring sinters form in one of the few environments where silica precipitation and silicification processes can be studied at the Earth’s surface, another environment being highly alkaline lakes. Consequently, they will remain important in studying how microbes and plants are silicified, both in modern environments and the geological record.

SKELETON

Biologically, a skeleton is a hard or rigid framework that could provide protection and support in many types of organisms. Most of skeletons are mineralized, but some may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, not including hydroskeletons. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites. Endoskeletons are internal hard parts (typical of many vertebrates). Most of endoskeletons are generally surrounded by skin and musculature. See entry "[Animal Skeletons, Advent](#)" for further reading.

SMALL SHELLY FOSSILS

Small shelly fossils (SSF, also "Small Shelly Fauna") is a non-taxonomic term, first used by Matthews and Missarzhevsky in the title of their review paper in 1975, to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites. See entries "[Animal Skeletons, Advent](#)" and "[Critical Intervals in Earth History](#)" for further reading.

SNOWBALL EARTH

Paul F. Hoffman
Harvard University, Cambridge, MA, USA

Synonyms

Cryochron; Global glaciation; Hard snowball; Ice-albedo catastrophe; Snowball (in geology); White Earth

Definition

Snowball Earth is a climate in which the oceans and most land areas are permanently covered by glacial ice. As less sunlight is absorbed by ice than by water or land, a critical area of ice will cause surface temperatures to fall below freezing everywhere, resulting in a snowball Earth. This arguably occurred near the beginning and end of the Proterozoic eon. Snowball Earths self-destruct after millions of years due to the buildup of atmospheric carbon dioxide of volcanic and metamorphic origin, which could not be converted into organic matter or limestone. Biological evolution is a postulated cause and consequence of snowball episodes.

History of the concept

Sedimentary deposits of glacial origin were first described from the late Proterozoic (Neoproterozoic) of Scotland in 1871 and from the early Proterozoic (Paleoproterozoic) of Canada in 1907. By 1940, it was apparent that the Neoproterozoic glaciation(s) had been more extreme than those of the Pleistocene and at least equal in severity to the late Paleozoic glaciations of Gondwanaland. In the 1960s, the occurrence of glacial deposits within thick successions of nearly pure carbonate strata suggested that Neoproterozoic ice sheets had entered what were normally the warmest parts of the globe. This was confirmed in the 1980–1990s by reliable paleomagnetic data showing that ice sheets had reached the ocean close to the paleoequator in the Neoproterozoic of Australia and Paleoproterozoic of South Africa (Evans, 2003). Moreover, evidence of marine geochemical anomalies concurrent with glaciation came increasingly to light in the form of sedimentary Fe_2O_3 and MnO_2 ore deposits, large excursions in stable carbon and sulfur isotopic compositions of minerals precipitated from seawater, and distinctive post-glacial "cap" carbonate sediments that rest directly on the terminal glacial deposit at all latitudes (Hoffman and Schrag, 2002). Neoproterozoic glacial deposits are now known from 22 different paleocontinents and microcontinents, and Paleoproterozoic deposits from 6.

The fraction of incoming solar radiation absorbed by ocean water under cloudless skies is 0.9, but for continuous ice it is only 0.4–0.6 and as low as 0.1 if the ice is covered by fresh snow. In the 1950–1960s, calculations by meteorologists of zonal average surface temperatures at different latitudes, assuming radiative energy balance and incorporating crude parameterizations of the radiative effects of clouds, meridional heat transport, and positive feedbacks due to the reflectivity (albedo) of ice, suggested that a lowering of solar luminosity by a few percent would result in a globe-encircling glaciation, or "white" Earth (North, 1990). If the luminosity is incrementally lowered, polar ice caps expand until their edges reach a critical latitude, beyond which ice advances rapidly to the equator without any additional luminosity reduction, or even with increased luminosity. This is due to runaway ice-albedo feedback – more ice reflects more radiation, creating more ice. (The same calculations indicated that a small increase in radiative forcing, due to anthropogenic CO_2 emissions for example, could cause a sudden loss of polar sea ice at a critical $p\text{CO}_2$ threshold.) These sensational findings greatly stimulated the nascent field of climate modeling, but proponents were puzzled how a "white" Earth disaster had been averted given that solar luminosity has increased by 25–30% over geological time (the so-called faint young Sun paradox). They assumed (incorrectly, as it turned out) that such an occurrence would extinguish all life – deep-sea chemoautotrophs and polar extremophiles were then unknown – and would be permanent because of the very large increase (~25%) in radiative forcing required to overwhelm a "white" Earth's high albedo.

As meteorologists assumed that a “white” Earth never occurred, they did not think to consult geologists, who remained oblivious to their findings.

In 1981, planetary scientists (Walker et al., 1981) proposed that Earth’s climate is modulated within the habitable range by a negative climate feedback resulting from the temperature-dependence of silicate-rock weathering. In the geochemical cycle of carbon, this is the means by which atmospheric CO_2 (dissolved in rainwater) is converted into bicarbonate ion (HCO_3^-), which dissolved in runoff makes its way to the ocean, where it is removed from circulation by the burial of carbonate sediments and organic matter. The feedback operates on a geological timescale ($\sim 10^6$ year) and causes the climate system to slowly seek whatever atmospheric CO_2 level, and hence climate, that is needed to balance the rate of CO_2 removal by silicate weathering with the rate of CO_2 emitted by volcanoes and metamorphic reactions. Walker et al. (1981) suggested that this feedback had prevented a “white” Earth disaster but noted that if one did occur, the consequent reduction of weathering rates would lead to an inexorable increase in atmospheric CO_2 as plate tectonics and therefore of CO_2 emissions would continue unabated. With the present emission rate and no CO_2 consumption, $p\text{CO}_2$ would increase to ~ 1.0 bar after 20 Myr. At some critical $p\text{CO}_2$, the “white” Earth would self-destruct violently due to ice-albedo and other positive feedbacks, leaving a transient aftermath in which high $p\text{CO}_2$, low surface albedo, and the recently deglaciated surface would conspire to cause intense weathering, exponentially lowering atmospheric $p\text{CO}_2$. The hysteresis loop in CO_2 versus planetary albedo means that a “white” Earth would be long-lived (10^6 – 10^7 year) but swift to melt (10^3 – 10^4 year), giving rise to a “greenhouse” transient (10^5 – 10^6 year). These are geologically testable predictions. But as the paleomagnetic evidence for global glaciation was not secure until 1986 (Evans, 2000), consideration of a self-reversing “white” Earth as a model for the geological record was delayed.

It was the paleomagnetist Joseph L. Kirschvink who first applied these concepts to low-latitude Neoproterozoic (Kirschvink, 1992) and Paleoproterozoic (Kirschvink et al., 2000) glaciations. He related the synglacial Fe_2O_3 and MnO_2 ore deposits to ocean stagnation and anoxia, caused by ice cover, which allowed the metals to be transported widely in solution in reduced form, and be precipitated upon deglaciation when the ocean was again ventilated. He predicted the global occurrence of sediments recording the abrupt climate switch at glacial terminations, later recognized as cap carbonates (Hoffman et al., 1998b). He speculated that an unusual preponderance of low-latitude continents (a situation that never occurred after 500 Ma) raised the planetary albedo to the critical threshold. He named the phenomenon “snowball” Earth as that is how the globe would appear from outer space. The name tacitly recognizes that the hydrological cycle, although greatly diminished on the cold solid

surface, would still be weakly maintained by sublimation and precipitation, not of snowflakes, but of tiny hexagonal snow prisms due to the global average surface temperature of around -50°C (Furukawa and Wettlaufer, 2007).

Number, age, and duration of snowballs

At least three snowball episodes are inferred from the geological record, two in the Cryogenian Period (~ 850 – 635 Ma) of the Neoproterozoic era ($1,000$ – 551 Ma), and one or more in the first half of the Paleoproterozoic era ($2,500$ – $1,600$ Ma). The 1.5×10^9 -year interval between older and younger snowballs is curiously devoid of glacial deposits. The timing of the youngest snowball is the best constrained and of the oldest the most poorly known. This is primarily a function of differences in their respective areas of preservation. Termination of the youngest snowball occurred in 635 Ma, coincident with the boundary between the Cryogenian and Ediacaran Periods (Knoll et al., 2006b). The age is based on ultra-precise (0.5 Myr uncertainty) U-Pb geochronology of primary zircons from volcanic ash-falls in Namibia and South China (Halverson, 2006). Sections in other regions are correlated with these based on synde glacial “cap” carbonates (see below), which are uniquely distinctive in many areas. The onset of the snowball is loosely constrained. It is younger than 654.5 ± 3.8 Ma in South China, based on ion-microprobe U-Pb geochronology (Zhang et al., 2008). The maximum duration of this snowball was 23 Myr.

The timing of the older Cryogenian snowball is weakly constrained (Halverson, 2006): its onset is younger than 726 ± 1 Ma in Oman and 725 ± 10 Ma in South China, and its termination occurred before 667 ± 5 Ma in the western USA. In Oman, strata within the glacial succession are no older than 713 ± 1 Ma. Interregional correlation of glacial strata is more uncertain than for the younger Cryogenian glaciation. There is fragmentary evidence for an earlier Cryogenian glaciation of presumed regional scale ~ 750 Ma in central and southern Africa, while a mid-Ediacaran glaciation of short duration occurred in eastern Newfoundland, Canada, at 582 Ma (Knoll et al., 2006b), with possible correlatives in western and northern Europe, central Asia, Western Australia, and southwestern Brazil.

Paleoproterozoic glacial deposits in the western Transvaal, South Africa, are interfingering with volcanic lavas erupted near sea level at $11 \pm 5^\circ$ paleolatitude (Evans et al., 1997) approximately 2.22 Ga (10^9 year before present) (Kopp et al., 2005). The duration of the low-latitude glaciation is unknown. Three distinct glaciations occurred between 2.45 and 2.22 Ga in the Huronian succession of Ontario, Canada, and correlative glacial deposits occurred in Wyoming (USA), Quebec (Canada) and possibly Finland (Ojakangas, 1988). The paleolatitudes of these deposits being unknown, they are assumed to represent regional-scale glaciations.

Paleogeographic reconstructions and paleoclimatic indicators in bounding strata

At the time of the Cryogenian snowballs, many continents were in low paleolatitudes and few if any were near the poles (Trindade and Macouin, 2007). This is consistent with cold climates because a preponderance of low-latitude continents maximizes the rate of atmospheric CO₂ consumption by silicate weathering. It was also a time of fragmentation and dispersal of the long-lived (1.0–0.8 Ga) supercontinent Rodinia (Li et al., 2008). Continental fragmentation also enhances silicate weathering by bringing land closer to the source of moisture. Cryogenian paleogeography contrasted with that of the late Paleozoic ice ages, when a supercontinent (Pangea) had just formed and the glaciated lands (Gondwanaland) lay in a polar region. Little is known of early Paleoproterozoic paleogeography, but there are suggestions that they accompanied the fragmentation of land-masses consolidated in the late Archean eon (2.7–2.5 Ga).

Cryogenian glacial deposits are found within thick successions of shallow-water carbonate rocks in Namibia, California, Arctic Alaska, and southern Mongolia (Halverson et al., 2005). This is paradoxical because non-skeletal carbonates form preferentially in the warmest parts of the surface ocean on account of their “reverse” solubility. Throughout Earth history, thick carbonate successions formed only at latitudes less than 35° (Ziegler et al., 1984; Opdyke and Wilkinson, 1990). Their range did not change between warmer and colder climates because their distribution depends on the relative not the absolute temperature. Thus the meridional temperature gradient has never been reversed due to high orbital obliquity (Evans, 2006), as has been proposed to account for low-latitude glaciation (Schmidt and Williams, 1995). If glaciers reached the ocean in the warmest areas of the world, then the colder areas must also have been frozen.

Sedimentology of the glaciogenic deposits

The sedimentology and inferentially the depositional processes of Proterozoic and Phanerozoic glacial deposits are quite similar (Boulton and Deynoux, 1981; Hambrey and Harland, 1981). Those more interested in the rocks themselves than in their distribution have a hard time believing that Proterozoic ice ages were different in character. They range from terrestrial lodgement, moraine and outwash (sandur) complexes to glaciomarine grounding-line wedges and fans, and proglacial suspension fallout with or without sediment gravity flows and ice-rafted debris (Kellerhals and Matter, 2003).

Shaped and striated clasts, subglacial pavements with grooves and chatter marks, and stratigraphic relations suggestive of ice streams (currents of fast-flowing ice within an ice sheet) all attest to dynamic glacial action (Hoffman, 2005). At first it was thought that dynamic ice sheets were inconsistent with a snowball because the frozen ocean could not resupply them with snow. However, climate models suggest that net sublimation of subtropical

sea-ice would supply ice sheets with up to centimeters of ice-equivalent annually, meaning that ice sheets would thicken sufficiently to generate dynamic ice streams within a few 10⁵ year, a fraction of the estimated snowballs duration (Donnadieu et al., 2003; Pollard and Kasting, 2004). Accordingly, the evidence for dynamic ice sheets is not incompatible with a frozen ocean.

On the Otavi carbonate platform of Namibia, the younger Cryogenian glaciation left a continuous grounding-line prism situated 500–1,000 m vertically below the rim of the platform (Hoffman, 2005). This is quite unlike any Quaternary ice grounding line in polar seas, which typically switched between the inner and outer shelf. The grounding-line prism in Namibia is directly overlain by a synde glacial “cap” dolostone (see below) deposited above prevailing wave-base, the only shallow-water deposit at such depth on the slope (Hoffman et al., 2007). This indicates glacioeustatic changes of >500 m, consistent with an average ice-sheet thickness of >1.1 km over all continents. An important implication of this finding is that shelves and platforms were above sea level during most of the glacial interval, and any glaciomarine deposits found there could only have been deposited when the deglaciation was well-advanced. The nature of such deposits has often been cited as inconsistent with snowball conditions (e.g., wave action, phototrophism, ice-rafting, etc.). This is true; by the time they were deposited, the snowball no longer existed.

Associated marine geochemical anomalies

Fe₂O₃- and MnO₂-ore formations

During the Fe-ore exploration boom following World War II, it was learned that the only “banded iron-formations” (BIF) younger than 1.9 Ga are intimately and exclusive associated with Cryogenian glacial deposits (Klein, 2005). Extensive ore-grade deposits of Fe₂O₃ (±MnO₂) were found in SE Australia, SW Brazil, NW Canada, and Namibia. The Australian and Canadian deposits are in the older Cryogenian assemblage, the Brazilian ones are in the younger(?) Cryogenian assemblage, and the Namibian deposits are in both(?). As only reduced Fe(II) is soluble in seawater, Martin (1964) attributed “this peculiar combination of sediments” to “oxygen deficiency in stagnating bottom waters caused by an ice cover.” Canfield and Raiswell (1999) pointed out that decreased continental runoff during a snowball would lower the influx of sulfate to the ocean, which after bacterial sulfate reduction, removes dissolved Fe(II) from seawater in the form of FeS₂ (pyrite). Lowering the influx of sulfate therefore raises the concentration of Fe(II). The large sea-level fall associated with a snowball also raises the Fe:S flux ratio in mid-ocean ridge hydrothermal vent fluids on account of the drop in hydrostatic pressure (Kump and Seyfried, 2005).

Kirschvink (1992) suggested that the dissolved Fe(II) was oxidized to insoluble Fe(III) at snowball terminations, consistent with the stratigraphic position of the Australian

BIF near the top of the glacial sequence. Elsewhere, BIF occurs as sporadic lenses within glaciomarine sequences and Fe oxidation may have been caused by discharging of oxic subglacial meltwater along the grounding lines of ice shelves.

The 2.22-Ga Makganyene glaciation in South Africa ended with outpourings of mafic lava and the deposition of major Fe- and Mn-ore deposits. The latter are the world's largest and imply the presence of abundant molecular O_2 (not required for Fe oxidation) ~ 0.22 Gyr after atmospheric O_2 first rose above 10^{-6} PAL (present atmospheric level) according to mass-independent sulfur isotope fractionation data (Farquhar et al., 2000). The youngest pre-Cryogenian BIFs are limited to collisional (foredeep) basins (1.89 Ga) around the Superior craton of North America, unrelated to glaciation.

"Cap" carbonates

"Cap" carbonates are highly continuous, meter- to decameter-thick layers of relatively pure carbonate lying sharply without significant hiatus on top of the last glacial deposits of a snowball (Hoffman and Schrag, 2002; Shields, 2005). They typically extend far beyond the actual glacial deposits at the same stratigraphic horizon.

The best developed cap carbonates are those associated with the youngest snowball deglaciation in 635 Ma: they are global in extent and sedimentologically unique in the entire stratigraphic column (Allen and Hoffman, 2005; Shields, 2005; Hoffman et al., 2007). They begin with a layer of pale gray, often pinkish, micro- and macropeloidal dolostone ($Ca_{0.5}Mg_{0.5}CO_3$). Its global average thickness is ~ 20 m and it was laid down diachronously, mainly above storm wave-base, during glacioeustatic flooding of continental margins and inland seas (Hoffman et al., 2007). Assuming that strong positive climate feedbacks (e.g., ice albedo, ice elevation, CO_2 degassing, gas-hydrate destabilization) drove snowball deglaciation on timescales < 10 kyr, cap dolostone accumulation rates were > 2 mm year $^{-1}$.

The dolostone contains anomalous sedimentary features such as giant wave ripples (Allen and Hoffman, 2005) and stromatolite biostromes containing strictly vertical tubes of internal sediment with meniscus-like laminae (Corsetti and Grotzinger, 2005). The top of the dolostone layer in some areas is marked by a continuous crust of primary seafloor $BaSO_4$ (barite) cement in the form of digitate rosettes (pseudostromatolites) with internal growth lamellae (Hoffman and Schrag, 2002). The barite crust and other redox-sensitive geochemical (Hurtgen et al., 2006) and biomolecular (Elie et al., 2007) proxies indicate that an oxic-anoxic interface within the water column intersected the seafloor at this horizon. In subsiding areas, the dolostone is overlain by deeper water shales or limestones, locally with layer-upon-layer of seafloor cements in the form of macroscopic crystal fans originally composed of aragonite, the orthorhombic polymorph of $CaCO_3$ (James et al., 2001). In

non-subsiding areas, the dolostone layer ends at a subaerial exposure surface heavily disrupted by products of phreatic and vadose diagenesis (Hoffman and Schrag, 2002; Shields et al., 2007).

The nature and extent of the 635-Ma cap carbonate indicates an ocean in which the mixed layer and thermocline waters were highly oversaturated with respect to $(CaMg)CO_3$ and $CaCO_3$ respectively. Sources of alkalinity responsible for the anomalous saturation state include the weathering of carbonate and silicate rock powder and debris exposed by deglaciation (Higgins and Schrag, 2003; Anderson, 2007), anaerobic oxidation of CH_4 released by melting of permafrost in organic-rich shelf sediments glacioeustatically exposed during the snowball (Kennedy et al., 2001; Jiang et al., 2003), and anaerobic respiration at depth of organic matter produced in surface waters newly exposed to sunlight (Font et al., 2006). It was suggested (Kennedy, 1996; Ridgwell et al., 2003) that the 635-Ma cap carbonate can be explained by analogy with the "coral reef hypothesis" of Quaternary glacial-interglacial cycles (Berger, 1982), in which alkalinity builds up in deep waters during glacial stages because of the loss of shelf area, where carbonate is normally sequestered without passage through corrosive deep waters. This mechanism presupposes continued carbonate production in open ocean surface waters during the glaciation, for which evidence is lacking.

The cap carbonate ending the older Cryogenian snowball is different in character but comparable in thickness to the one just described, as well as in its sharp basal contact. Lithologically, it is usually a dark, fetid, limestone or dolostone, locally rhodochrosite ($MnCO_3$), deposited below storm wave-base. Former aragonite seafloor cements are prominent in some areas, notably in eastern Brazil (Vieira et al., 2007). In Namibia, there are hundreds of meters of continuous sublittoral microbialaminates with distinctive roll-up structures (Hoffman et al., 1998a). Missing altogether is the transgressive cap dolostone characteristic of the 635-Ma deglaciation. Carbonate production evidently did not begin until after deglaciation was complete, suggesting a weaker alkalinity flux into the ocean or a lower saturation state when the deglaciation began.

Cap carbonates a few centimeters to decimeters thick occur locally above the mid-Ediacaran (582 Ma) and early Cryogenian (~ 750 Ma) glacial deposits, believed to represent regional-scale glaciations.

In the Paleoproterozoic, the middle Huronian glacial formation has an impure cap limestone up to 17 m thick, the only carbonate unit in a terrigenous clastic succession up to 12 km thick (Bekker et al., 2005). The low-latitude Makganyene glaciation (~ 2.22 Ga) in South Africa has a possible cap carbonate (Mooidrai Formation) known only from subsurface bore holes (Kirschvink et al., 2000).

Post-glacial isotopic anomalies

Cap carbonates are typically depleted in ^{13}C (i.e., $\delta^{13}C < 0.0\text{‰}$ PDB) and detailed studies of expanded

sections of the 635-Ma cap carbonate in different areas show large negative isotopic excursions (Halverson et al., 2005). Excursions are deviations over time in a positive (higher $\delta^{13}\text{C}$) or negative direction, followed by a return to previous values. The excursion begins $\sim 0\text{‰}$ at the base of the oldest (deepest) cap dolostone, descends through the cap dolostone to a low of -6‰ in the basal limestones (after a $\sim 1.5\text{‰}$ step-function across the dolostone–limestone transition), and then rises slowly back to $\sim 0\text{‰}$. Its stratigraphic thickness depends on the sedimentation rate: on the Otavi platform, Namibia, it is ~ 400 m thick but only ~ 50 m thick on the deeper slope sections (formerly the ice grounding-line zone). The origin of the excursion is disputed (e.g., Kennedy et al., 2001; Higgins and Schrag, 2003).

The same cap carbonate hosts negative excursions in $\delta^{11}\text{B}$, interpreted as an expression of greatly elevated $p\text{CO}_2$ (Kasemann et al., 2005), and $\delta^{34}\text{S}$ of carbonate-associated sulfate (CAS), interpreted as oxidized sulfidic snowball waters (Hurtgen et al., 2006). The negative $\delta^{34}\text{S}$ excursion is followed by a positive one with lows and highs of 15 and 45‰, respectively. The positive values (the highest in Earth history) are attributed by a rapid increase in isotopic fractionation between sedimentary sulfate and pyrite, without a compensatory decline in the fractional burial rate of pyrite (Halverson and Hurtgen, 2007).

The older Cryogenian cap carbonate preserves only the rising leg of the post-glacial isotopic excursions, reflecting stratigraphic truncation (non-deposition) during glacioeustatic flooding. Surface waters became strongly enriched ($\delta^{13}\text{C} > 4\text{‰}$) again soon after carbonate production resumed (Yoshioka et al., 2003). Paired negative and positive $\delta^{34}\text{S}_{\text{CAS}}$ excursions resemble those above the younger snowball but data are fewer (Hurtgen et al., 2002).

The two known Paleoproterozoic cap carbonates are also depleted in ^{13}C (Kirschvink et al., 2000; Bekker et al., 2005), but lack local isotopic context as they occur in clastic-dominated successions. A major positive $\delta^{13}\text{C}$ excursion (Lomagundi excursion) appears to begin before age-equivalents of the Makganyene glaciation in North America (Bekker et al., 2006).

Pre-glacial isotopic anomalies

Both Cryogenian snowballs were preceded by long ($>10^7$ year) intervals of consistent isotopic enrichment ($\delta^{13}\text{C} \geq 5\text{‰}$ PDB), followed by Myr-long excursions to much depleted values ($\delta^{13}\text{C} \leq -5\text{‰}$), variably truncated by subglacial erosion. There is no accompanying $\delta^{34}\text{S}$ excursion. The excursions largely predate sea-level falls due to ice-sheet growth. Schrag et al. (2002) suggest that the prolonged isotopic enrichment reflects high fractional organic burial due to rapid sediment burial and expanded suboxic zones on preponderantly low-latitude continental margins. They propose that this situation ultimately led to a slow rise in atmospheric CH_4 due to methanogenesis in

organic-rich sediments. The rise in CH_4 is held responsible for the negative $\delta^{13}\text{C}$ excursion (Halverson et al., 2002). Silicate weathering feedback would lower $p\text{CO}_2$ in response to a slow rise in CH_4 , causing the climate to become more unstable because of its greater sensitivity to CH_4 concentration and the absence of buffering of its concentration by the ocean. Greater stochastic variability in a cold climate increases the risk of exceeding the critical threshold for runaway ice-albedo feedback. Unusual stromatolite and oolite development during the pre-glacial negative $\delta^{13}\text{C}$ excursions could reflect a rise in pH caused by the proposed lowering of $p\text{CO}_2$. The methane substitution model (Schrag et al., 2002) may not be viable, however, because it depends on an unrealistic residence time for CH_4 in the Cryogenian atmosphere of $>10^5$ year. Unless their timing around 1 Myr before the onsets of both Cryogenian snowballs is a coincidence, or merely wrong, the negative $\delta^{13}\text{C}$ excursions should have some bearing on snowball causation.

Climate modeling

Climate models are used to simulate the conditions under which a snowball could initiate, develop over time, and deglaciate. Ideally, an atmospheric general circulation model (AGCM) would be coupled to a dynamic ocean model, a dynamic ice-sheet model, a dynamic sea-ice model, and an interactive model of the geochemical cycle of carbon. In reality, this is computationally unattainable in the foreseeable future. To begin with, full-blown AGCMs are typically run to equilibrium over ~ 100 model years, which are ~ 4 orders of magnitude less than the adjustment time for the geochemical carbon cycle. Therefore, atmospheric CO_2 concentrations are either prescribed at various levels, providing “snapshots” under arbitrary conditions, or else a greatly simplified AGCM must be employed.

Snowball climate models must be adjusted for ambient Proterozoic conditions. Solar luminosity was $\sim 7\%$ lower than present in the Cryogenian and 16–20% lower at 2.22 Ga (Crowley and North, 1991). The Earth’s rotation rate was $\sim 10\%$ higher in the Cryogenian (Williams, 2000) and faster by an unknown amount in the Paleoproterozoic. And Proterozoic continents had higher albedos in the absence of forest cover. These factors all tend to lower the global mean surface temperature and would have resulted in compensatory higher levels of atmospheric CO_2 (Walker et al., 1981).

Modeling suggests that while snowball initiation is resisted by ocean dynamics (Bendtsen, 2002; Poulsen and Jacob, 2004), it is assisted by atmospheric Hadley convection (Bendtsen, 2002), flowage of ice-shelf ice (Goodman and Pierrehumbert, 2003), and wind-driven sea ice (Lewis et al., 2007). Both the thickness of tropical sea ice and the CO_2 level required for deglaciation are highly sensitive to the prescribed ice albedos (Warren et al., 2002; Pollard and Kasting, 2005; Lewis et al., 2006; Le Hir et al., 2007). The role of clouds is complex

and is a major source of uncertainty in the models (Pierrehumbert, 2005).

Theories of causation

In addition to the methane substitution model described above, a number of other astronomical, oceanographic, geodynamic, and biological theories have been proposed to account for low latitude glaciation. Astronomical theories include solar variations (Harland, 1964), large orbital obliquity (Williams, 1975), ice-ring collapses (Sheldon, 1984), impact ejecta (Bendtsen and Bjerrum, 2002; Fawcett and Boslough, 2002), and passage through giant molecular clouds (Pavlov et al., 2005). The large obliquity hypothesis is the most testable and contested of these models (Néron de Surgy and Laskar, 1997; Williams et al., 1998; Pais et al., 1999; Maloof et al., 2002; Levrard and Laskar, 2003). Oceanographic theories include enhanced carbonate burial (Roberts, 1971), intermittent ocean stagnation (Kaufman et al., 1993; Grotzinger and Knoll, 1995), glacioeustatic hypsometry change (Ridgwell et al., 2003), and enhanced organic burial (Kaufman et al., 1997). Geodynamic theories involve continental distribution (Kirschvink, 1992; Schrag et al., 2002), supercontinent breakup (Donnadieu et al., 2004), flood-basalt weathering (Goddéris et al., 2003), and true polar wander (Li et al., 2004). Biological theories include the evolution of biocatalyzed weathering (Carver and Vardavas, 1994), methane destruction (Pavlov et al., 2000, 2003; Catling et al., 2001; Claire et al., 2006), methane substitution (Halverson et al., 2002; Schrag et al., 2002), and the evolution of oxygenic photosynthesis (Kopp et al., 2005). As the ultimate cause of the Quaternary ice ages remains obscure, it is not surprising that the “why” question for Proterozoic snowballs is undecided. Different snowball may have had different causes, but whatever their cause, it was an uncommon occurrence.

Snowballs and the history of oxygenation

There is increasing evidence for stepwise increases in environmental oxygenation near the beginning and end of the Proterozoic eon, roughly contemporaneous with the inferred snowballs. This is the empirical motivation for causative theories involving the oxidative destruction of reduced “greenhouse” gases (Pavlov et al., 2000, 2003; Catling et al., 2001; Kopp et al., 2005; Claire et al., 2006). To make a climatic impact, changes in oxygenation must occur rapidly ($<10^6$ year), or else silicate weathering feedback will cause compensatory adjustments in $p\text{CO}_2$, largely nullifying the effect on radiative forcing.

Mass-independent sulfur isotope fractionation data indicate that atmospheric O_2 concentrations remained below 10^{-6} PAL (present atmospheric level) until ~ 2.45 Ga, close to the first Huronian glaciation and ~ 230 Myr before the Makganyene snowball. The same data suggest the possibility that O_2 remained very low

(but $>10^{-6}$ PAL) during the intervening interval. However, deposition of the succeeding Kalahari MnO_2 -ore formation required at least transient O_2 concentrations >5 orders of magnitude higher than this, possibly caused by a photosynthetic “bloom” and resultant organic burial in the snowball aftermath (Kirschvink et al., 2000) or by H_2O_2 (hydrogen peroxide) released by the melting of snowball ice (Liang et al., 2006).

There is increasing evidence that the deep oceans remained anoxic, but sulfidic not ferrous, during most of the 1.5 Gyr ice-age gap between the Makganyene and the Cryogenian snowballs (Scott et al., 2008). Mass-dependent S-isotope data imply that seawater sulfate concentrations remained low (<4 mM) between the Cryogenian snowballs (Hurtgen et al., 2002), but rose rapidly to near modern (29 mM) levels in the early Ediacaran (Halverson and Hurtgen, 2007). This rise in marine sulfate, presumably caused by increased atmospheric $p\text{O}_2$, appears to follow rather than lead the end-Cryogenian snowball. However, the response time between oxygenation and methane destruction is much shorter than between oxygenation and growth of the marine sulfate reservoir, so an increase in oxygenation to trigger the snowball is not ruled out by these data.

Implications for evolutionary biology

Eukaryotic survival

The younger Phanerozoic glaciations had little impact on the course of biological evolution as measured by rates of origination or extinction of taxa: only the Hirnantian (latest Ordovician) glaciation ~ 445 Ma was accompanied by major mass extinctions. Snowballs, however, presented qualitatively different challenges to existing biota, if they actually occurred. For millions of years, mean annual surface temperatures at the equator would have resembled those of Antarctica today. Areas where sunlight and liquid water coexisted were severely limited, hot springs and zones of perpetual crack development where mobile sea ice encountered fixed rocky substrates. With permanent ice cover, seawater would be starved of oxygen, becoming anoxic due to sinks for oxygen in the ocean. It would become progressively more acidic due to submarine volcanic CO_2 emissions and air-sea gas exchange through cracks at rates lower than the oxygen consumption rate. The geochemical response of the ocean to these afflictions is complex, but seawater pH would probably be lowered by 2.0–2.5 pH units (Le Hir et al., 2008). Deep-sea vent biota would be adversely affected by reduced Eh and pH gradients between hydrothermal fluids and seawater. With low overall productivity, nutrient levels would be high, except for fixed nitrogen due to denitrification. Upon deglaciation, a “bloom” of primary producers would occur, contingent upon nitrate availability. The bloom might be delayed because meltwater injection and surface warming would combine to produce an unusually stable density stratification (Shields, 2005), temporarily suppressing nutrient-upwelling from depth. A 635-Ma

cap carbonate in southwestern Brazil preserves a molecular record of this bloom in the form of an unusual assemblage of biomarkers pointing to a low-diversity eukaryotic flora dominated by red algae and a prokaryotic biota rich in green sulfur bacteria (Elie et al., 2007). The latter imply anoxic waters at the base of the photic zone and the former are consistent with low levels of illumination as exists, for example, in a turbid water column.

No biologist doubts that prokaryotic life, bacteria and archaea, could survive a snowball cryochron and its aftermath. Some do question if eukaryotic algae could survive (but see Vincent et al., 2004). As several extant clades of eukaryotic algae evolved before the Cryogenian, their survival causes some to doubt the existence of snowballs (Knoll, 2003). This is the attraction of more benign but less physically plausible climate states like “slushball” Earth, wherein continents are glaciated at all latitudes (satisfying geological observations) but half of the ocean remains ice-free (Peltier et al., 2004). However, the slushball solution provides no satisfactory explanation for synglacial Fe- and Mn-ore deposits (Klein, 2005), for cap carbonates (Pollard and Kasting, 2005) or for the multimillion-year duration of Cryogenian glaciations inferred from stratigraphic subsidence analysis (Hoffman and Schrag, 2002).

The only fossil record that is sufficiently continuous to bear directly on the evolutionary impact of snowballs is the record of organic-walled, acid-resistant microfossils representing a variety of eukaryotic algae, protists, and possibly fungi (Knoll et al., 2006a). Their Proterozoic record is characterized by extremely low rates of turnover (extinctions and originations) of taxa, roughly 100× slower than in the Ediacaran and Phanerozoic, following the last snowball (Peterson et al., 2005). The sparser macrofossil record is also consistent with slow turnover. Taxonomic diversity drops precipitously during the interval that includes the Cryogenian snowballs (Knoll et al., 2006a), with the inevitable result that it is little studied by palynologists. There have been no systematic studies to determine if the interval of very low diversity actually begins at the first Cryogenian snowball. The microfossil record effectively starts only after the Paleoproterozoic snowball (Knoll, 2003).

Evolutionary innovation

Since the mid-twentieth century, geologists have speculated that Neoproterozoic glaciation and its aftermath was somehow responsible for the advent of multicellular animals, the first fossils of which were known to occur not too far above the glacial deposits in many areas (Harland and Rudwick, 1964). (Note this was not the advent of multicellularity *per se*, which occurred earlier in algae (Knoll, 2003).) In the 1990s, with improvements of radiometric dating, this connection appeared less likely: the canonical Cambrian “explosion” in diversity of animal taxa with hard parts did not occur until ~530–520 Ma and

the oldest macrofossils arguably attributable to metazoans, the enigmatic Ediacara biota, appear ~580 Ma. This is >100 Myr and 55 Myr, respectively, after the last snowball ended in 635 Ma. In contrast, molecular divergence in modern animals, calibrated by known branching points in the geological record (so-called molecular “clocks”), gave estimates of animal origins much older than the Cryogenian snowballs.

However, recent evidence from microfossils and molecular fossils appears to put the connection back in play once again. In South China, remarkable cysts enclosing metazoan diapause eggs and embryos extend down to strata deposited within ~3 Myr (632 Ma) of the last snowball termination in the same area (Yin et al., 2007). In Oman, molecular fossils (24-isopropylcholesterol) believed to be diagnostic of sponges are found down to and even within correlative glacial deposits (Love et al., 2009). In addition, new molecular “clock” analyses place the origin of eumetazoa more in line with the new fossil evidence (Peterson and Butterfield, 2005), while the molecular signature of animal radiation indicates a geologically instantaneous event (Rokas et al., 2005).

How might the environmental stress of a snowball and its aftermath have contributed to revolutionary biological innovation? One idea involves the dual role of heat-shock protein 90 (HSP90) in suppressing the expression of mutant signal transduction proteins and in promoting the proper folding of stress-damaged proteins (Baker, 2006). Under extreme temperatures, HSP90 is diverted from the former role in favor of the latter, allowing accumulated cryptic mutations to be phenotypically expressed and therefore subject to natural selection. Another possibility is that spatial isolation of biological refugia in a snowball favored the evolution of altruism, a basic requirement for intercellular cooperation, by promoting kin selection and eliminating non-altruistic invaders (Boyle et al., 2007).

The evolutionary impact of the Paleoproterozoic snowball(s) is even more conjectural as there is no detailed fossil evidence for synchronicity. Nevertheless, it has been suggested that horizontal gene transfer between taxa at levels higher than at the species level was triggered by environmental catastrophes, and that these gene exchanges were responsible for such macroevolutionary innovations of possible Paleoproterozoic age as thermophilic and photosynthetic bacteria, and the eukaryotic cell (Hartman, 2002). Molecular fossil evidence for an Archean (pre-snowball) origin for oxygenic photosynthesis and for eukaryotes has been presented (Brocks et al., 1999; Summons et al., 1999); however, more recent studies suggest that the “biomarkers” in question are less phylogenetically diagnostic than earlier believed (Fischer et al., 2005; Kopp et al., 2005; Rashby et al., 2007). Finally, the surprising finding that the highest 18S rRNA gene diversity in extant protists and the richest in ancestral lineages occurs in Arctic communities (Stoeck et al., 2007) suggests the possibility that snowballs figured prominently in their evolution.

Conclusion

Important new evidence for extreme atmospheric carbon dioxide concentrations during and after the Marinoan snowball Earth has recently been obtained from mass-independent oxygen isotope ratios in sulfate minerals (Bao et al., 2008, 2009).

Summary

Virtually all continents were covered by large ice sheets during two discrete intervals of the Cryogenian Period (between 725 and 635 Ma). The multimillion-year duration of the glacial intervals, the deposition of syn-glacial Fe₂O₃ and MnO₂ sedimentary ores in different areas and of post-glacial “cap” carbonates at all latitudes support the hypothesis that the world ocean was also ice-covered. These episodes represent a climate state unknown on Earth since 635 Ma, or in the 1.5 Gyr before 725 Ma. Climate models indicate that the pan-glacial climates, popularly known as snowball Earth, were the result of runaway ice-albedo feedback, and that they were reversed by infra-red radiative forcing due to the accumulation of atmospheric CO₂ of volcanic-metamorphic origin, which could not be removed because of the absence of liquid precipitation when surface temperatures were below freezing everywhere. New microfossil and molecular biomarker evidence opens up the possibility that the origin of multicellular animals was related to these climate shocks. Evidence for glaciation at low paleolatitudes around 2.22 Ga, also associated with sedimentary Fe and Mn ores, suggests the existence of snowball states possibly related to the initial rise of atmospheric O₂.

SODA LAKES

Stephan Kempe¹, Jozef Kazmierczak²

¹University of Technology, Darmstadt, Germany

²Polish Academy of Sciences, Warszawa, Poland

Definition

The term “soda lake” designates a class of lakes with waters showing an excess of the total alkalinity ($TA \cong [HCO_3^-] + 2[CO_3^{2-}]$, i.e., the sum of the charges of the bicarbonate ion plus carbonate ion) over the charges of the alkaline earth ions magnesium and calcium:

When such water is evaporated, the high $[CO_3^{2-}]$ concentrations will cause a rise in pH and eventually, Na carbonates precipitate. These are soda (or natron, $Na_2CO_3 \cdot 10H_2O$, monoclinic), trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, monoclinic), and thermonatrite ($Na_2CO_3 \cdot H_2O$, orthorhombic). They are commercially used in the glass-, textile-, paint-, soap- and metal-industry, mined worldwide (Garret, 1992).

Occurrence

Soda lakes occur worldwide, albeit in very specific zones: they seem to be associated with active tectonic and volcanic zones (Figure 1). Most of the famous soda lakes occur in East Africa along the East African rift (e.g., Kraml and Bull, 1998/1999). Here, the succession of soda lakes left deeply buried soda deposits that also serve as the source of natro-carbonatite lavas (Ol Doinyo Lengai Stratovolcano, Tanzania). Another well-known group of alkaline lakes, some fossil such as Searles Lake, occur in the western USA. Less well known are lakes on the Altiplano, or in Australia, Afghanistan, Turkey, and other places around the world. So far no comprehensive list of soda lakes has apparently been compiled.

Setting

However, there seem to be two different types of lakes that acquire soda chemistry: most of the larger lakes are depressions in endorheic regions closed toward exorheic runoff by tectonic movements or by volcanic dams. The ratio between the tributary area and lake surface area is large. The largest soda lake on the Earth is Lake Van (Van Gölü) in eastern Anatolia (e.g., Kempe et al., 1991). Table 1 gives its morphometric data; it is (because Lake Aral dried up) by volume the third largest closed basin lake on Earth. Lake Van occupies the former headwaters of the Euphrates before it was dammed by an eruption of the Nemrut volcano.

The other class of soda lakes occur in volcanic craters or calderas. They typically do not have any surface tributaries and their ratio between recharge area and lake surface area is small. We have discovered the alkaline nature of several crater lakes, including Satonda Crater,

Soda Lakes, Figure 1 The global distribution of some of the major soda lakes or soda lake groups and their relation to margins of tectonic plates.

Soda Lakes, Table 1 Lake Van morphometric data

Total basin area	16,096 km ²
Total tributary area	12,574 km ²
Lake surface	3,522 km ²
Lake volume	576 km ³
Lake maximum depth	451 m
Annual water exchange	3.78 km ³
Altitude of lake level	1,648 m a.s.l.

Source: Kempe and Kazmierczak (2003); Compiled from Reimer (1995)

Indonesia (Kempe and Kazmierczak, 1993), Niuafo'ou Caldera Lake, Tonga (Kazmierczak and Kempe, 2006), and Kauhako Crater Lake, Molokai, Hawaii (unpublished data and Donachie et al., 2004). Other soda lakes occupy the Empakai Crater in Kenya, the crater in Pantelleria, and possibly a score of other craters that have not been investigated as yet. Even Santorini, Greece, must have had an alkaline crater lake for some period prior to the famous Minoan eruption that blew out the stromatolites of that lake.

Chemistry

Soda lakes can reach pH in excess of 10.5 and alkalinities of >150 meq/l. Some of the most alkaline water bodies are Lake Magadi (Eugster, 1986) in Kenya and Mono Lake in California (e.g., Bischoff et al., 1993). Lake Van has a pH of 9.7 and an alkalinity of 151 meq/l (Kempe et al., 1991; Reimer et al., 2009). These are examples of highly alkaline lakes. But there are soda lakes “in the making,” i.e., lakes that obey the basic condition of $TA > (Mg + Ca)$ but have not acquired higher salinities. One of them is the crater lake of the Nemrut Volcano itself that has dammed Lake Van. In Table 2 the water of Lake Van is compared with that of the Nemrut Lake.

The Table lists the main parameters that are used to characterize natural waters, all in all the two lakes are not very different in their respective surface and bottom samples, i.e., they are relatively well mixed. First of all the conductivity gives a rough measure of the amount of total salts dissolved, which is in seawater about 35 g/l, in Lake Van it is about 22 g/l, and in Nemrut Lake only about 440 mg/l, i.e., Nemrut Lake is what would be classified as a “fresh water” lake. But this is only one of the criteria: when calculating the soda lake criterion

(i.e., $TA/(Mg + Ca)$) we find 16.65 and 16.85 for Lake Van (0 and 440 m, respectively), 3.11 and 3.18 for Lake Nemrut (10 and 150 m, respectively) and 0.018 for seawater. This ratio tells us that Lake Van is a typical soda lake with >16 times as much alkalinity as alkaline earth ions, but that also Lake Nemrut is a soda lake with >3 times higher alkalinity than alkaline earth ions; whereas seawater has much more Mg and Ca than dissolved carbonates (i.e., >54 times). We also see that the chemical

composition of both lakes do not differ much with depth, apart from the pH in Nemrut Crater that drops considerably. Lake Van has a very high pH as expected from its high alkalinity. But Nemrut crater lake has – at the surface – the same slightly alkaline pH as seawater, not identifying it (yet) as a soda lake. When from these data (and temperature not given here) the CO_2 pressure of the water (PCO_2) is calculated (using PHREEQE; Parkhurst et al., 1990) and compared to the PCO_2 of the atmosphere of

Soda Lakes, Table 2 Chemical composition of Lake Van, the largest contemporary soda lake, compared to Nemrut Crater Lake, a “soda lake in the making” and to modern seawater

Lake/Depth	pH	PCO_2 ppmv	Alkal. meq/l	Cl meq/l	SO_4 meq/l	Na meq/l	Mg meq/ l	Ca meq/l	Cond $\mu S/cm$	SI_{Cc}	SI_{Ara}	SI_{Dol}

Soda Lakes, Table 3 List of modern soda lakes with $CaCO_3$ precipitation in comparison with modern oceanic conditions

Site	Minerals dominating	Saturation index	Kind of $CaCO_3$ precipitate	Source
North Sea 1986	Calcite	0.375–0.904 Cc mean of 122 samples: 0.567	Biomineralization of coccolithophorids	Pegler and Kempe, 1988
Bahamas banks	Aragonite	0.47–0.6 Ara	Extremely low rates (if any) of aragonite (not the reason of whittings)	Morse et al., 2002
Satonda crater lake	Aragonite, Calcite	0.98 Cc, 0.84 Ara	Biomineralization by red algae and cyanobacterial sheaths	Kempe and Kazmierczak, 1993; Kazmierczak et al., 2004
Lake Van	Aragonite, Calcite	1.14 at 0 m to 1.06 at 440 m Cc, 0.99–0.91 Ara 4.09–3.81 Dol	Permineralization of cyanobacterial sheaths, inorganic chemical gardens, river plume whiting, summer whittings	Kempe et al., 1991; Reimer, 1995; Kazmierczak et al., 2004; Reimer et al., 2008
Lake Tanganyika	High-Mg Calcite	0.96 Cc	Five zones of massive thrombolites down to 50 m	Kempe and Kazmierczak, 1990 and citations therein
Andros Island	Low-Mg Calcite	Upon degassing and evaporation 1.14 Cc	Inland lakes with weakly calcified cyanobacterial and algal mats	Same as above
Walker Lake	Low-Mg Calcite	1.11 Cc, 0.95 Ara, 3.90 Dol	Small cabbage-like stromatolites up to 4 cm high, built by filamentous green alga and oscillatorian and coccoidal cyanobacteria.	Same as above; Kempe and Kazmierczak, 1997
Mono Lake Figure 2 top	Aragonite (Ikaite)	1.24 Cc, 1.09 Ara, 3.74 Dol	Large tufa columns at former groundwater outlets	Kempe and Kazmierczak, 1997; Bischoff et al., 1993
Pyramid Lake Figure 2 bottom	Calcite	1.36 Cc, 1.21 Ara, 3.89 Dol	Huge towers and mounds at former groundwater outlets	Benson, 1994; Arp et al., 1999
Niuafou, crater lake	Aragonite	0.65 Cc, 0.50 Ara, 2.65 Dol	Head-like stromatolites built by coccoid and filamentous cyanobacteria	Kazmierczak and Kempe, 2006
Kauhako crater lake	Calcite	0.97 Cc, 0.82 Ara	Calcified sheaths of filamentous cyanobacteria	Kempe, unpublished

Cc = calcite; Ara = aragonite; Dol = dolomite

380 ppm, then we find that the crater lake has a much higher PCO_2 than the other samples, indicating that it receives volcanic CO_2 from subsurface springs, while Lake Van does not.

PHREEQE also allows for calculating the state of saturation of water with respect to minerals. The saturation index (SI) is defined as the logarithm of the ion activity product divided by the solubility constant of a given mineral (here, for calcite as an example):

$$SI_{\text{calcite}} = \log([Ca^{2+}] * [CO_3^{2-}] / K_{\text{calcite}}).$$

The SI yields negative values if water is undersaturated, zero if saturated, and positive values if supersaturated. The results (Table 2) show that all samples, with the exception of the deep Nemrut sample, are oversaturated with respect to calcite, aragonite, and dolomite. But when the deep Nemrut sample is numerically degassed, it will also show high carbonate supersaturation (last line in Table 2). The main difference between Lake Van and seawater is that the carbonate supersaturation (which is >10 times its saturation) of Lake Van allows for in situ precipitation of aragonite, while in seawater, even though supersaturated, no spontaneous precipitation occurs. Rather, the supersaturation of seawater is kept low by the multitude of enzymatically biomineralizing organisms that are generally absent in soda lakes due to the high alkalinity.

Soda lake microbialites

Those of the mature soda lakes that reach high supersaturation values (i.e., above $\approx SI\ 0.8$, Kempe and Kazmierczak, 1990) produce cyanobacterial microbialites. Table 3 lists

a few of them for which sufficient geochemical data are available to calculate saturation. The water analysis available for Andros Island originally do not show supersaturation, but the permineralizing cyanobacterial mats grow in ephemeral very shallow nonmarine inland lakes that apparently sustain growth only after an extensive evaporative phase. In case of one of the Niuafu'ou caldera lakes (Vai Lahi), the current water composition also does not sustain in situ permineralization, and the stromatolites discovered there stopped growing about 200 years ago. Overall, soda lakes represent the best sites to study modern stromatolites, their structure, microbial ecosystem, and growth rates. Many of them have shown to produce structures strikingly similar to those of Precambrian microbialites.

Genesis of soda lakes

These data presented here and in the cited papers show that soda chemistry can arise in various climatic, geologic, and morphologic settings. We find water bodies that are soda lakes in the making that will eventually acquire mature soda chemistry, such as Nemrut Crater Lake, a lake that originated only a few hundred years ago after the last eruption of the Nemrut caldera. Other crater lakes, such as Lake Taupo in New Zealand, will never reach this state, since they have an outlet. Astonishing is also the fact that Lake Kivu and Lake Tanganyika (both with an outlet) have soda lake characteristics (Soda Lake Index for Tanganyika: 1.5) and (at least in Lake Tanganyika) grow microbialites.

It has long been stated that the type of chemistry is dependent on the proportions of the ions in the waters

Soda Lakes, Figure 2 Calcareous tufa towers in Mono Lake (*top*) and Pyramid Lake (*bottom*). These towers originally formed under water at inlets of groundwater.

delivered to it (Garrels and Mackenzie, 1967). Eugster and Hardie (1978) constructed flow diagrams that show the various possibilities of brine evolution. In case of soda lakes, the criterion is the ratio of TA/(Mg + Ca). From the distributions of the soda lakes along the plate boundaries it appears that this ratio most likely arises in areas with fresh volcanic rocks. Here, biogenic CO₂ and/or (see Lake Nemrut) volcanic CO₂ can react with fresh silicates, mobilizing Na, K, Mg, and Ca, in the necessary proportions. Ongoing weathering within the crater lakes and their hydrothermal system (as in the case of Niuafu'ou), or continuing evaporation in the terminal lakes will then lead to mature soda lake chemistry and to a CaCO₃ supersaturation of around SI = 1 that will sustain microbialite growth. However, this is only a very broad picture. When looking at Satonda and Kauhako crater lakes, we find involvement of a second process that causes the alkalinity to rise. This is sulfate reduction. Both lakes are marine-derived lakes, i.e., are filled originally with sulfate-rich seawater. Microbial disintegration of organic matter must replace the charge of the sulfate ion with that of bicarbonate ions according to

This pathway of alkalinity production in anaerobic water bodies was coined “alkalinity pump” (Kempe, 1990; Kempe and Kazmierczak, 1994), supplementing the shift toward a soda chemistry, where sulfate is available.

Summary

Soda lake waters show an excess of the total alkalinity over the charges of the alkaline earth ions magnesium and calcium ($[\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] > 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}]$). They are characterized by high pH values (increasing with evaporation) and, eventually, precipitation of Na carbonates. Mature soda lakes that reach high supersaturation values with respect to calcite, aragonite, and dolomite (above $\approx$ SI 0.8) may produce cyanobacterial microbialites. The ubiquitous soda lakes in areas with fresh volcanic rocks and high weathering potential and the microbialites found therein gave rise to the *Soda Ocean Hypothesis* (see separate entry), stating that the early ocean, by following simple geological rules, should have been highly alkaline, possibly similar to present Lake Van.

SODA OCEAN HYPOTHESIS

Stephan Kempe¹, Jozef Kazmierczak²

¹University of Technology, Darmstadt, Germany

²Polish Academy of Sciences, Warszawa, Poland

Definition

The “soda ocean hypothesis” (SOH) stands for the concept of an early (i.e., in essence Precambrian) alkaline or even highly “alkaline ocean,” in analogy to the chemistry of the present-day “soda lakes.”

Soda ocean hypothesis (SOH)

The SOH has been advanced in biology (e.g., Snyder and Fox, 1975) for biochemical reasons before it was developed in earth sciences for geochemical reasons (Kempe and Degens, 1985; Kempe et al., 1989; Kempe and Kazmierczak, 1994).

In *biology*, the SOH rests on the observations that certain reactions considered essential for biogenesis would be favored by alkaline conditions (e.g., Abelson, 1966). One of those is the experimental observation that peptide bonds are more stable in alkaline than in acidic environments (e.g., Dose and Rauchfuss, 1972).

In *earth sciences*, the SOH rests on elemental mass balances, thermodynamic and kinetic arguments, and the analogy to modern soda lakes. These arguments are in short:

1. A CO_2 -rich atmosphere in the presence of water would react vigorously with the highly meta-stable, widespread, fine-grained glassy silicates from impacts and volcanic eruptions as would be present during the period of the terminal cataclysm in the Hadean. Carbonic acid weathering of silicates (“Urey Reaction”) will liberate cations in equivalence to the consumed carbonic acid, producing bicarbonate and carbonate as anions.
2. Continental silicate weathering today (aided by high soil PCO_2 due to biological activity; $\text{PCO}_2 = \text{CO}_2$ Pressure) consumes annually $0.15 \cdot 10^9 \text{ t C}$ (Hartmann et al., 2009); thus today’s volume of atmospheric CO_2 would be consumed in about 5,000 years by the Urey Reaction. This rate suggests that a high PCO_2 atmosphere is not stable on geological timescales.
3. Other primordial acids, such as HCl , have much less mass and therefore the primordial ocean must have had TA (total alkalinity $\equiv [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] > [\text{Cl}^-]$).
4. Sulfur-based acids were not available in larger quantities since not enough free oxygen was in the system to allow formation of either sulfurous or sulfuric acids.
5. The entire mass of carbon available in crustal compartments (i.e., $65.5 \cdot 10^{21} \text{ gC}$) as carbonates and organic carbon today could in principle have been dissolved as alkali carbonates in the oceans - as long as H_2O and CO_2 were degassed at similar rates - because this would amount to $48.5 \text{ gC/kg H}_2\text{O}$ while Na_2CO_3 is solvable at $53 \text{ gC/kg H}_2\text{O}$ (Kempe and Degens, 1985).
6. Observations of modern soda lakes show that their tributaries have inputs of $[\text{Na}^+] + [\text{K}^+] > [\text{Cl}^-] + [\text{SO}_4^{2-}]$ and $[\text{Ca}^{2+}] + [\text{Mg}^{2+}] < [\text{TA}]$ (Garrels and Mackenzie, 1967). When evaporated these waters will become alkaline because Ca and Mg carbonates (and sulfates in modern settings) will reach saturation first and Na and K carbonates will stay in solution causing increasingly higher alkalinity and pH. Soda lakes (i.e., lakes with an excess in Na-carbonates) almost exclusively occur today in or near volcanic regions. The early ocean (as well as possible primordial oceans on other planets such as Mars; Kempe and Kazmierczak, 1997) could have reacted the same way, storing CO_2 as TA as quickly as CO_2 was degassed from the mantle or deposited on Earth by comets.

These arguments are based on simple acid–base reactions but have several *derivatives*:

1. The atmosphere could not have had a high enough PCO_2 to counterbalance the lower insolation of the “faint early sun”.
2. In alkaline waters SiO_2 can be kept in solution in high concentrations (at least in the primordial seas where

- silica-sequestering organisms such as sponges, diatoms, silicoflagellates, and radiolarians were absent).
3. The higher the TA becomes, the lower the concentration of the free Ca-ion will become because of the fact that the IAP (the ion activity product) governing CaCO_3 solubility, i.e., $\text{IAP} = [\text{Ca}^{2+}] \cdot [\text{CO}_3^{2-}]$ is dominated by the carbonate ion.
 4. In the absence of biologically controlled biomineralization (as was typical for the entire Precambrian until, at the onset of the Cambrian, enzymatic biocalcification evolved) the ocean must have been of a very high supersaturation, since the spontaneous precipitation of CaCO_3 -minerals is kinetically inhibited in natural settings. Saturation is most commonly expressed as the saturation index (SI), i.e., the quotient between the IAP and the solubility product of the mineral (K_{Mineral}). $\text{SI} = \log \text{IAP}/K_{\text{Mineral}}$. A survey of nonenzymatic carbonate CaCO_3 -precipitating environments (Kempe and Kazmierczak, 1990; Kazmierczak and Kempe, 2006) shows that these environments have an SI of +0.8 to +1 (i.e., a 10-times supersaturation) while the modern ocean has a much lower supersaturation (North Sea $\text{SI}_{\text{calcite}}$ average summer 1986 = 0.567 ± 0.096 ; Pegler and Kempe, 1988) because it is controlled by enzymatic reactions and not by inorganic precipitation. Dolomite can be supersaturated to $\text{SI} = 4$, i.e., 10,000 times its solubility product in soda lakes (e.g., Kempe and Kazmierczak, 2007). This fact, i.e., the higher carbonate mineral supersaturation of the primordial ocean is today accepted widely (e.g., Grotzinger, 1990; Arp et al., 2001).

Because the soda ocean has vanished and the present day halite ocean prevails, there must have been a transition between the two (Figure 1). This transition must have been driven by a process with a long time constant. This process

Soda Ocean Hypothesis, Figure 1 Simple representation of the timing of the rise and fall of the soda ocean due to the Urey reaction. The happy face marks the onset of multicellularity triggered by a massive increase of the free calcium ion towards the end of the Precambrian.

is thought to be the subduction of seawater with marine crust and sediments in subduction zones and the consecutive formation of continental crust. About 1 km^3 of seawater is subducted per year today. Any compound dissolved in the ocean has therefore a half-life of about 1 billion years, depending on the rate of subduction. Thus the soda ocean could in fact have prevailed for several billion years before being gradually diminished. According to the soda ocean model (Kempe and Degens, 1985), Na and K would have been transferred into feldspars of continental granodiorites and the carbon would have been deposited as CaCO_3 and kerogen on the continents where they are stored for longer times than deep sea deposits that are lost to subduction within less than 100 million years. The chloride subducted would be recycled as volcanic HCl, in a cycle quicker than continental weathering.

Consequences for biogenesis

The alkaline model has also a series of consequence for *biogenesis* and the evolution of life in the first 3.5 billion years of Earth history.

1. Thermodynamic calculations show that in highly alkaline solutions (up to the saturation of Na_2CO_3), the free $[\text{Ca}^{2+}]$ can be as low as $4 \cdot 10^{-7} \text{ mol}$ (Kazmierczak and Kempe, 2004), while, due to ion-pairs, total Ca is significantly higher. In the model calculation shown in Figure 2 seawater (i.e., a solution with high chloride and sulfate) was mixed with the natron-saturated solution based on the dilute water from Nemrut Crater Lake (-10 m), a “soda lake in the making” (see entry “*Soda Lakes*” Table 3) that leads to a free $[\text{Ca}^{2+}]$ of $1.5 \cdot 10^{-6} \text{ mol}$. Very low environmental Ca^{2+} concentrations are favorable for biogenesis because cells have to maintain a $[\text{Ca}^{2+}] < 10^{-6} \text{ mol}$ in their cytosol (e.g., Kretsinger, 1983; Carafoli, 1987). Otherwise, the proteins would be denaturalized and lose their ability to function. Thus the formation of life in an acidic and consequentially high $[\text{Ca}^{2+}]$ environment is even more difficult to understand.
2. The only macroscopic fossils throughout the Precambrian (with the exception of the Ediacara fauna and some problematic biostructures) are microbialites (stromatolites, thrombolites), biosedimentary structures produced by colonies of microorganisms. The majority of researchers accept that they have formed by the permineralization of the EPS of biofilms dominated by cyanobacteria (e.g., Riding, 2000; Altermann et al., 2006). This form of CaCO_3 -precipitation is nonenzymatic and the cyanobacteria do not instrumentalize these precipitates for functions. The high CaCO_3 -supersaturation caused by the alkaline marine condition is thus an environment in which these microbialites could have thrived easily. Today soda-lake microbialites are formed by the same processes (e.g., in Lake Van, Kempe et al., 1991; López-García et al., 2005, in Mono Lake, and in Niufo’ou caldera lakes, Kazmierczak and Kempe, 2006) while today’s

Soda Ocean Hypothesis, Figure 2 PHREEQUE mixing experiment of modern seawater (*left*) with the natron saturated Nemrut Crater Lake water (see Table 2 in entry “*Soda Lakes*”) (*right*), illustrating the possible transition of an alkaline ocean (*right*) to one dominated by halite and gypsum (*left*). After linear mixing of constituents, the solutions are adjusted to have a calcite saturation index of +1 and a $p\text{CO}_2$ of 3.5 (roughly the present atmospheric PCO_2). Note that the sharp drop in Ca concentration is accompanied by only a slight increase in alkalinity. Note also that the sulfate concentration would describe an exponential curve between 50 and 100% if subsamples were calculated for that section of the mixing experiment.

marine stromatolites are apparently growing predominantly by trapping and binding of allogene particles (e.g., Ginsburg, 1991).

- For three billion years cyanobacteria seem to be among the primary photosynthetic organisms. Most modern cyanobacteria are alkalophiles, suggesting that their evolution proceeded in alkaline environments.
- The development of eukaryotic organisms in the late Palaeoproterozoic may have also been triggered by the early ocean conditions: The gradual increase in the $[\text{Ca}^{2+}]$ ambient concentration due to the slow transition between the soda and halite dominated oceans, could have caused the geochemical stress that might have influenced the evolution of a cell nucleus by protecting the genetic material against the disruptive Ca^{2+} -influx.
- And even the onset of multicellular organisms may have been triggered by the increasing $[\text{Ca}^{2+}]$. Experiments with sponges suggest that adhesion of cells can be triggered by an increase in $[\text{Ca}^{2+}]$ in the environment (e.g., Kretsinger, 1977). Thus the appearance of faunas in Ediacara times may be the indication that the soda ocean was near its demise.
- The biomineralization that appears in many different taxa at the turn of the Precambrian/Cambrian is, in view of the SOH, a detoxification reaction to the

rapidly rising $[\text{Ca}^{2+}]$ when the ocean, as TA decreases (e.g., from 10.3 to 2.38 meq/l as in present seawater), goes through a sort of titration endpoint triggering a >10-fold increase in $[\text{Ca}^{2+}]$ (Kempe and Kazmierczak, 1994). Measurements of Ca in fluid inclusions seem to give this facet of the SOH credibility (Brennan et al., 2004; Petrychenko et al., 2005).

Counterarguments

Some arguments against the SOH were brought forward. These, however, do not really disprove the SOH:

- Models of early Earth often prescribe a long-lasting high PCO_2 -atmosphere to keep the oceans from freezing. However, it may also be argued that the lack of free oxygen in the oceans and atmosphere could have allowed for higher methane concentrations that prevented permanent freezing of Earth.
- Möller and Bau (1993), Bau and Möller (1994) state that the water of Lake Van has a positive cerium anomaly but Precambrian carbonates (or BIFs) do not. However, these authors compare water with sediments. Measurements showed that Lake Van sediments do not exhibit the same anomaly as the water body (own data, unpublished).

Outlook

The *acceptance of the SOH* in the literature is mixed. Some authors agree with it in essence (Arp et al., 2001), others accept certain aspects (such as the high CaCO_3 -supersaturation; Grotzinger and Kasting, 1993; Riding, 2000; or Mg/Ca ratios; Ries et al., 2008), and some doubt its relevance and follow own modeling lines (e.g., Morse and Mackenzie, 1998). Many papers deal with questions of the rising oxygen and sulfate, redox-reactions or certain sedimentary problems like BIF-formation or microbialite (stromatolite) structures without recurring to the overall chemical evolution of the ocean. Although the majority of researchers tend to ignore the SOH, it found entrance into several textbooks of general geology (Degens, 1989; Einsele, 1992; Bahlburg and Bretkreuz, 1998). Digital modeling appears to be not of much help - apart from stating thermodynamic conditions correctly - since the results depend on the adopted boundary conditions of the Hadean and Archean environment, which are as yet not well defined. For example, when prescribing certain PCO_2 values to avoid freezing of oceans because of the faint early sun, then no highly alkaline ocean can evolve. Future research will have to show which one of the many models explains the past of our planet and its geological and biological evolution best.

Summary

Resting on elemental mass balances, thermodynamic and kinetic arguments, and the analogy to modern soda lakes, the soda ocean hypothesis (SOH) states that the Precambrian ocean was alkaline, with a total alkalinity $> \text{Ca} + \text{Mg}$

and a high supersaturation of carbonate minerals (SI ca. 1). The soda ocean was lost slowly by subduction of seawater and replaced by the present halite-dominated ocean toward the end of the Precambrian. This facilitated the development of multicellularity and biomineralization as detoxification reactions of life against the rising Ca-concentrations. The SOH is also consistent with the widespread occurrence of stromatolites and cherts in the Precambrian.

Definition

Soil: refers to the product of mineral weathering and secondary mineral formation, (microbial) mineralization, humus formation, and the resulting element mobilization/immobilization in the upper Earth crust in a pedogenetic process involving chemical, physical, and biological activities.

Introduction

Soil is the basis of terrestrial life, particularly for agriculture, forestry, and generally land-use by man (Driessen et al., 2001). It is also the largest terrestrial ecosystem dominated by high numbers of microorganisms and soil-living animals as well as the root systems of plants. The biota within this ecosystem, not only interact but also actively shape their environment (Fiedler et al., 2002). This can be easily seen with root systems or earthworm/mole tunnels, but the metabolic activities of microorganisms by far exceed these visible alterations. Microbes are essential for the decomposition of plant litter followed by humification. The pedogenesis differs with respect to base rock material, climatic conditions, and other factors leading to soil series of different soil types. Root exudates as well as microbiological acidification and release of

chelating agents take part in mobilization and immobilization processes of mineral elements, essential or ecotoxically relevant alike, and thus are major players in import into food chains, and input into water paths or as volatiles into the atmosphere.

Soil function

The soils of the world can be characterized from a more structural or a more functional point of view (FAO-UNESCO, 2002), and the geobiologically important functions involving metabolically active soil dwellers are characterized with reference to microbiology, botany and agriculture, and zoology.

Soil function is essential for plant nutrition. The capacity to solubilize nutrients like P and minerals including K, Na, Mg, Ca, and trace elements, as well as availability of S or N are largely the product of microbial mobilization from minerals, microbial degradation of organic matter, or fixation from air (e.g., for nitrogen). Soil mineralogy largely determines the buffering capacity for minerals adsorbed to different fractions (Jones and Bassington, 1998). The sustainability of microbial activity is connected to water availability for growth, and water storage and availability are also major functions for plant growth. Detrimental processes of soil degeneration like soil acidification, desertification, clay mineral destruction, or decrease of organic contents are global problems mankind experiences which will have a large impact on socioeconomic scales.

Agriculture and nutrition in modern systems are coupled to the use of fertilizers and plant protection chemicals which can constitute a threat to the water pathways, if management of agricultural use is not performed according to the laws and provisions on soil and water protection, good agricultural practice, or integrated farming, and monitoring has to be included to ensure best practice. Soil density increases due to the use of heavy machinery which leads to soil degradation in high-yield agricultural systems the world over.

In order to assess possible problems with land-use and soil degeneration, soil science has provided a very good reference system to classify and monitor soils based on soil mechanics, soil physics, soil genesis, soil composition, and soil functions reviewed in different contexts below (IUSS Working Group WRB, 2006). As soil can be regarded as a major sink for carbon depending on land-use, this might become more important as climate change discussions are gaining impact. Generally, soils and larger views on landscape should be regarded as eminent players in global cycles (Meir et al., 2006).

Soil texture

The soil texture can be divided in the proportion of sand (S: 63 μm –2 mm), silt (U: 2–63 μm), and clay (T: smaller than 2 μm) after removing skeleton particles (larger than 2 mm). While sand soils have more than 70 volume % of sand, clay soil is mainly composed of clay (>50%) with

only small portions of sand (<20%). Most soils in humic conditions are sandy loam (with at least 1/3 sand, 1/3 silt, and up to 1/3 loam) or sandy silt soils (with at least 1/3 sand, at least 1/3 silt, and lower amounts of loam).

These differences in texture are also reflected in mineral composition of the respective soils. While sand soil contains 80% of quartz, this mineral constitutes only 25% of clay soil. In contrast, 50% clay minerals (mostly illit and vermiculite, as well as smaller portions of montmorillonite and kaolinit) are present in clay soil while sand soil contains only 5% of clay minerals. As clay minerals show the highest buffering potential for water and mineral elements, like alkali and earth alkali elements, soil types with higher clay mineral contents show high sorption capacities. Sandy loam/silt shows the highest fertility because of a harmonized ration between water storage and sorption capacities.

Water-retention potentials are of major importance for soil functioning. While sand soil has a water capacity of only 10 volume %, 2/3 of that water (7 volume %) is bio-available. Loam has 45 volume % water capacity of which, however, only a small proportion, usually less than 12 volume %, is available to plant roots. Sand soil has the highest aeration with 30 volume % of gas-filled pores. This is dependent on the pore sizes. Pores that are smaller than 10 μm retain water. Large pores of over 50 μm diameter, in contrast, are air-filled and contain only adsorption water. Capillary water in unsaturated soil is found in pores of 5–10 μm diameter. This is important for the soil function with respect to plant growth. As plant root hairs can just about enter pores of 5–10 μm , most water transport in soil is not simply taken from water-filled pores, but has to be extracted with sucking tension. The investigation of in situ soil water, however, remains a challenge (Weihermüller et al., 2007).

Soil type

Soil types are distinguished depending on the development of soil (pedogenesis) over space and time. The formation of a soil type generally takes a long time, upward of 1000 years. The soil type also is dependent on the climatic conditions under which the pedogenesis has taken place. A typical example of this is the formation of laterite soils in tropical areas. Such soil types show strong coloration, with iron-rich red soil types dominating in most areas. This is due to mobilization and wash-out of elements released from minerals and retaining of insoluble iron(hydroxy)oxides.

The function of mineralic, climatic, and biological conditions over time leads to formation of soils defined by different horizons. These can extend over cm up to 100 m and more, depending on the conditions experienced.

Horizons and soil profiles

A visual inspection of a soil profile already leads to immediate distinction of several layers in a typical soil. In an autochthonous soil formation, the lowest typical layer

above groundwater is the C horizon, the base rock on which the soil develops. It presents the basis for the elemental composition of the soil developing on its surface.

The B horizon (subsoil) is the next layer, clearly dominated by weathering products. Immigration of clay and sesquioxides (Fe and Al-oxihydroxides) may be found to dominate such B horizons which is specified in B_v (weathering dominated), B_t (loam accumulation), and B_s (sesquioxides) subclassification.

The uppermost layer is the A horizon (topsoil) which is rich in humus resulting from degradation of leaf litter and often shows a darker color due to organic contents enriched in this horizon. The uppermost layer of humus also is specifically termed A_o horizon. In the A horizon, microbial populations are largest and metabolic activities of soil microorganisms can be shown easily by soil respiration analyses. The A horizon also is the site of dominant plant root penetration which again stabilizes and supports the soil structure as well as the microorganisms present. Again, this horizon can be subdivided into layers A_h or A_1 (uppermost layer rich in humus), A_p (altered upper layer due to ploughing) and A_e or A_2 (subsequent layer influenced by wash-out processes). A layer of litter above the topsoil horizon is formed by decaying plant material. Depending on soil type, not all horizons have to be present.

Soil biology

The animals found in soil, or edaphone, are earthworms, nematodes, insects, specifically collembolids, and moles, to name the most prominent. Their function in soil is especially to mix the soil, to draw leaves under the soil surface which accelerates decay because of higher humidity and better accessibility for microbes, and to form passages for water interflow allowing rain to enter a soil more easily.

Plant roots stabilize soil and protect from wind and water erosion. Decaying plant roots leave passages also allowing for preferential water flow. And living roots contain special tissues for aeration and therefore improve oxygen availability for microorganisms in soil. At the same time, up to 30% of plant net photosynthesis products can be excreted by the roots in the root exudates. These consist mainly of organic acids, like acetate, oxalate, malate, and citrate. These are able to feed microbes in the rhizosphere and also chelate iron and supply the plant with iron. On the other hand, these organic acids, as well as sugars and amino acids form root exudates, provide nutrition for soil microorganisms which multiply in the vicinity of roots. This constitutes the rhizosphere, the specific area found around a plant root (Watt et al., 2006). More directly associated with the plant root are the rhizoplane bacteria which colonize the surface of the plant root. Symbiotic root associations include the nitrogen-fixing rhizobial symbioses with leguminaceous plants, and the mycorrhizal mutual symbioses between fungi and plant roots. It has been stated that microbial populations structure the plant biodiversity seen above-ground by such soil-derived associations (van der Heijden et al., 2007).

The soil surface, if no plants are present, is often covered by a crust consisting of a biofilm with cyanobacteria, fungi, bacteria, and lichens. This crust will lead to covering of bare soils which will then be prone to succession with mosses and plants.

Soil microbiology

Soils are the major place of element turnover and biogeochemical cycling in terrestrial ecosystems (Crawford et al., 2005). The degradation of plant litter, decay of leaves, carcasses, feces, and wood rotting are maintained by soil microorganisms with subsequent processes of humification. In addition, denitrification, nitrogen fixation, and element mobilization are performed by the metabolic activities of soil microorganisms. The formation of humus and the binding of elements with humic and fulvic acids drive soil development, and its function for the soil ecosystem cannot be overestimated.

Populations of soil microorganisms contain eukaryotes, bacteria, and archaea. Depending on the metabolic functions prevailing, the soil generated at the site will be dominated by formation of humic and fulvic acids, like in moorlands, by high mobilization of cations, and the formation of dissolved organic matter (DOC) in luvisols and podzols (in woodlands) or tchernozem (in agricultural land and grasslands). To have an idea of the scale, in 1 hectare soil it has been calculated that 8 tons of microorganisms are present, while the edaphon makes only for 2 tons of biomass. With the smaller size of microbes, this makes for very high numbers of soil microorganisms consisting of eukaryotic, bacterial, and archaeal cells.

The eukaryotic population is dominated by fungi with minor populations of ciliates, flagellates, algae including oomycetes and amoebae including myxomycetes. Of special importance are the mycorrhizal fungi forming a mutual symbiosis with plant roots thereby influencing not only plant physiology, but also soil as the hyphae extending into soil can add to soil structure and texture (Rillig and Mummey, 2006).

The archaea found in soil include especially the anaerobic methanogens which can lead to methane exhalation. However, methane oxidation performed by other groups of related archaea, already sequester a large portion of methane in soils. Methane exhalation is more often seen from swamps and flooded areas.

The major taxa of soil bacteria are the Gram-negative proteobacteria, the cytophaga, and Gram-positive bacilli and actinobacteria. Microbial interactions are a driving force for the community structure (Wardle, 2006). Per gram dry weight of soil, usually 10^7 – 10^9 bacteria are found. However, the bacterial population so far mainly had been analyzed by plating techniques, which will allow only those to be found that are growing under the applied laboratory conditions. Estimates of direct counts have indicated higher numbers with only 1–10% of bacteria being cultivable. Modern techniques relying not on cultivation but on DNA extraction from soil with subsequent

amplification and cloning of 16S rDNA sequences give a better insight in microbial soil populations. New taxa occur by these analyses and the phylogenetic associations observed from the obtained 16S rDNA sequences show that entire branches in the phylogenetic tree of bacteria can be described. It will remain a task to now find possibilities to cultivate these organisms in order to evaluate their physiological properties. Only such new investigations will allow to assess the role of new classes of bacteria in soil function and specific pathways for microbial degradation and soil formation will be uncovered as such investigations and modeling making use of the results will progress (O'Donnell et al., 2007).

Humification

Soil organic matter is the basis for humification (Kögel-Knabner et al., 1990). The characteristics of soil organic matter have been analyzed in some detail (Schaumann, 2006). Humus (Stevenson, 1994) provides essential functions in soils. The formation of humic acids and fulvic acids is essential for A horizon development, and especially the A_h horizon of tchernozem is rich in humus. Both humic acids (brown and grey) and shorter-lived fulvic acids have been described as recalcitrant matter with turnover times of thousands of years. These figures are re-evaluated now as it becomes clear that microbial metabolism uses these recalcitrant substrates and incorporates the carbon moieties into their cell mass. However, it is clear that the humic and fulvic acids constitute a major portion of soil matter and that their specific function in water retention and mineral element adsorption contributes a great deal to soil fertility.

Humus constituents also are important for (temporal) fixation of minerals and organic exudates. Their release will be controlled by the microbiota prevalent in the environment (Watteau and Berthelin, 1994).

Summary

Soil is the basis of terrestrial life and both evolves from biological activities and in turn allows and shapes terrestrial ecosystems. Soil types can be distinguished with different compositions, functionalities, and fertilities for production in agronomy and forestry, or water quality. The development of a soil type, such as tchernozem, rendzina, and podzol (and in tropic conditions, latozol) is dependent on base rock, climate, physical and chemical weathering, and formation of humic substances which takes thousands of years. The pedogenesis, in addition, is a result of root functions and plant litter degradation. The resulting soil can be characterized in vertical direction by soil horizons, which are distinguished from the A horizon with high humus contents, over a B horizon with lower humus contents, to the C horizon mainly consisting of base rock material. Soil series attempts to combine soil types and soil structure to reveal parameters for soil function.

SPECIES (MICROBIAL)

Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization; thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy. See entry “*Microbial Communities, Structure, and Function*” for further reading.

SPELEOTHEMS

Roman Aubrecht
 Comenius University, Bratislava, Slovakia

Synonyms

Cave deposits; Cave sinters

Definition

The word “speleothem” is from Greek and means “cave deposit.” According to its origin, this term can be used for any cave deposits, but it is used mostly for secondary mineral deposits formed (precipitated) in caves. In this entry, speleothem is understood as constructively formed, new cave material. Materials originated by destructive phenomena, such as erosion, weathering, etching, biocorrosion, or bioerosion are not subjects of this entry.

Biogenic and abiogenic speleothems

Most of the speleothems originate inorganically by precipitation of various minerals from solutions. The minerals are dissolved by undersaturated fluids and precipitate when the solutions become supersaturated, e.g., by evaporation, outgassing, or pH changes. Mineralogical compositions of speleothems vary depending on the environment in which the caves are formed. The most common speleothem-forming mineral is calcite (as most of the caves are formed of limestones), forming well-known sinter forms, such as dripstones (stalactites, stalagmites) and flowstones. Locally, mostly in hydrothermally influenced cavern systems, speleothems may be formed by its rhombic modification – aragonite. Gypsum and other sulfate minerals commonly form speleothems in gypsum karst but are widespread also in other types of caves. Speleothems formed in silicate rocks (e.g., sandstones, quartzites, granites, etc., [Figure 1](#)) are relatively rare, composed mostly of various forms of silica (from opal-A to microquartz depending on its recrystallization). Other speleothems can be represented by ferroan and manganese oxides and hydroxides forming cave flowstones.

Speleothems, Figure 1 Examples of microbial speleothems – cave stromatolites encrusted by silica in the sandstone cave Cueva Charles Brewer, Chimantá Plateau, Venezuela. (a–c) Mushroom-like stromatolites growing on the cave walls. (d) Slabs of stalactitic and mushroom-like stromatolites. Columnal stromatolites (*dark*) are formed by filamentous microbes; *white*, chalk-like parts represent stromatolites formed by tiny spherical microbial colonies. (e) Other shape of stromatolites with prevailing laminae formed by filamentous microbes.

Overall inventory of cave minerals is very large (for a summary see Hill and Forti, 1986).

The formation of some speleothems is influenced by organisms. The organisms can be passively covered (encrusted) by speleothems or they can directly biologically mediate their formation. In some cases it is not easy to distinguish between the active and passive role of the organisms. Biological mediation of mineral precipitation usually involves biomineralization (biomineralization (general aspects); microbial biomineralization; silica biomineralization (sponges)) and/or organomineralization. Biomineralization means direct precipitation of mineral skeleton (either internal or external) or encrustation by the organism itself (*syn vivo*). Organomineralization in

which the precipitation of minerals is mediated by organic matters produced by the organisms and by changing the ambient conditions (e.g., pH, enrichment or depletion of the solution by metabolism, etc.). They can occur either *syn vivo* (when the organisms are alive – they influence the ambient environment actively) or *postmortem* (after the organisms are dead – the ambient environment is influenced by the decay products of the organisms).

Organisms which mediate speleothem formation

The speleothem-forming organisms are mostly microorganisms (Archaea, Bacteria including Cyanobacteria, and Algae); more evolved multicellular organisms are

mostly represented by Fungi, mosses and lichens. Also roots of higher plants, penetrating to caves can form speleothems. All the mentioned organisms form speleothems from the autochthonous cave material (mostly taken from solutions). Excrements of animals (e.g., bats) can turn to well-known cave deposit – guano. Unlike the previously mentioned speleothems, guano and its minerals (rich group of phosphates, nitrates, and organic minerals) are completely allochthonous in caves, introduced originally from outside.

Microbes

Microbes inhabiting caves are mostly chemolithoautotrophic or chemoheterotrophic, i.e., their nutrition is not dependent on sunlight (for review see Konhauser, 2007). The exception is the so-called lampenflora, represented by phototrophic cyanobacteria and other algae which live on the lightened places in show caves. Phototrophic microorganisms normally inhabit the entrance areas and the number of microorganisms declines rapidly toward the twilight areas. Unicellular algae – diatoms – were found to contribute to the formation of speleothems, which occurred close to the entrance (Kashima et al., 1987; Kashima and Ogawa, 1995). Some cyanobacteria, although originally phototrophic, can adapt themselves to darkness and change their life mode to heterotrophic. For instance, the genera *Fisherella* and *Calothrix* were found to be able to change their mode of life to slow heterotrophic in complete darkness (Whitton, 1987). Some cyanobacteria were found to inhabit dark cave environment e.g., *Geitleria calcarea* and *Scytonema julianum* (Friedman, 1955; Bourrelly and Depuy, 1973) and contribute to speleothem formation. *Nostoc* is also easily adaptable to a heterotrophic mode of life, and is a common symbiont (endobiont) in lichens and higher plants. In addition to photosynthesis, *Nostoc* is able to perform nitrogen fixation (symbiosis of higher plants with *Nostoc* provides them with nitrate). *Nostoc* has also been reported from caves in Israel, growing in various zones, from well illuminated to complete darkness (Vinogradova et al., 1998). Moreover, *Nostoc* is also supposed to form large opal stromatolites in the Venezuelan sandstone caves (Figure 1; Aubrecht et al., 2008).

The most common in cave environments are chemolithoautotrophic and chemoheterotrophic microorganisms. Similar to other microorganisms, they use CO₂ as their carbon source but their source of energy comes from different chemical reactions. Chemoheterotrophs utilize preformed organic compounds, whereas chemolithoautotrophs utilize mostly inorganic compounds (Konhauser, 2007). These organisms and processes they utilize are numerous but only some of them are important speleothem-forming factors. Sulfur-oxidizing bacteria, such as *Beggiatoa* or *Thiothrix*, are responsible for deposition of elemental sulfur and sulfates in caves. They are particularly important in the caves with sulfur-rich waters, e.g., Parker Cave, Kentucky (Barton

et al., 2001). Bacteria also mediate formation of iron oxide and manganese oxide flowstones (Gradziński et al., 1995). Finally, they may also mediate formation of the carbonate speleothems, which are the most widespread speleothems in the world (Taboroši, 2006).

Fungi

Fungi are ubiquitous in all caves, being mostly chemoheterotrophs. They not only inhabit the caves but they actively contribute to the formation of some carbonate speleothems, such as a particular, soft form of sinter – moonmilk (Gradziński and Szulc, 1997; Gradziński et al., 1997).

Mosses

Mosses (often together with lichens) occur mostly in the near-entrance areas and are mostly passively encrusted by minerals (mostly calcite), thus forming moss tufas (Taboroši, 2006).

Plant roots

In shallow-placed galleries, plant roots sometimes penetrate from the surface. They are often mineralized, forming the so called rootsicles (Taboroši, 2006). It is not yet known whether they represent passive encrustations, or the roots actively mediate the precipitation. This is also true for other plant (and animal) remnants which are locally transported to the caves from the surface.

Marine organisms forming speleothems

Marine organisms represent a special chapter in the genesis of organic-mediated speleothems. Marine water, bringing nutrition to submarine caves, enables many organisms to live in this cryptic environment. Sessile organisms overgrowing the cave walls easily turn into speleothems. Very common are cryptic stromatolites (Reitner, 1993) formed by nonphotosynthetic organisms or serpulid buildups (Taboroši, 2006; Schlögl et al., 2008) formed by these filter feeders in submarine caves.

Methods of recognition of the speleothem-forming microorganisms

Cave-dwelling microorganisms, including those which contribute to speleothem formation, are considered to be extremophiles. That means they are organisms living in and adapted to environments which are not prolific for many organisms and which lack many aspects necessary for life; in caves, it is mainly the lack of sunlight and generally oligotrophic character of the environment. Adaptation of these organisms to the cave environment makes them uneasy to be determined by classical microbiological methods (Barton, 2006). For instance, for the complete identification of cyanobacteria, about 37 characteristics are needed, e.g., cell morphology, ultrastructure, morphology of colonies or filaments, genetic characteristics (DNA), cultivation conditions, and life conditions (Castenholz, 2001). Cultivation was so far the most

important tool in microbiology. This tool was developed mostly for medical purposes and was optimized for the research of microbes inhabiting animal bodies. However, only a small portion of free-living microbes is cultivable from environmental samples, including caves. Therefore, new culture-independent *in situ* methods have been developed for the detection of microbial groups in natural microbial assemblages, based on the molecular analysis of their DNA (Barton, 2006). Among these methods, one of the most important is *in situ* hybridization (FISH). Biomarker analysis may also be a suitable tool for the analysis of speleothems, in which only organic matter remained after dead, decayed organisms.

Conclusion

Speleothems are secondary mineral deposits formed in caves. They can form either inorganically or originate biologically. The inorganic formation pathway is based on physical precipitation from solutions after they become supersaturated. Biologically mediated precipitation is influenced by organic matter produced either by living or dead organisms and does not necessarily involve supersaturated solutions. This kind of precipitation acts via biomineralization or organomineralization, and may result in various sorts of minerals, such as calcite, elementary sulfur, sulfates, iron and manganese oxides, etc. The main biological protagonists forming speleothems are microbes. They are mostly chemolithoautotrophic and chemoheterotrophic microorganisms, or phototrophic organisms that changed their life modes and adapted themselves to the cave environment. Normally, the phototrophs are active only in near-entrance parts of caves. Other organisms forming speleothems are mosses, lichens, higher plants, or animals. These are however, mostly passively encrusted by minerals; their potential for active biological mediation to form speleothems is still the matter of research.

Synonyms

Sponge-associated bacteria; Sponge-associated microbes; Sponge-associated microbiota; Sponge bacteria; Sponge-microbe systems; Sponge symbionts

Definition

Sponges are sessile multicellular aquatic animals (Lat. Porifera = bearing pores) whose bodies have a typical body plan which allows water to pass through the animals. Sponges are characterized by a skeleton made of calcareous, siliceous spicules or horny fibers.

Sponge microbes: Bacteria and archaea that live in close and permanent association with sponges, usually in the mesohyl between sponge cells.

Introduction

Sponges are sedentary benthic organisms found in shallow waters on tropical coral reefs to the Arctic and the deep sea. Some species, however, are restricted to freshwater ecosystems. Sponges are characterized by a typical body plan built around a system of water canals and chambers (Figure 1a). Within the chambers, flagellated cells called choanocytes produce a water current that enters the sponge body through surface pores (ostia) and leaves through larger openings called oscula. Hence, sponges are filter feeders and incorporate particles from the water as energy and nutrient source. An external cell layer (pinacoderm) encloses the sponge mesohyl, a glycosidic matrix containing several cell types which perform a variety of functions. Sponge cells show a low degree of specialization and a high degree of independence so that the sponge body in some respect resembles a protozoan colony. However, sponges are, without any doubt, placed as true members of the Metazoan (Ax, 1995; Müller, 1998a, b).

Sponges have been grouped into three classes: Calcarea, Hexactinellida, and Demospongiae. Calcarea are characterized by the presence of calcareous spicules. The upgrade of this class to the phylum level has recently been proposed by Borchiellini et al. (2001). Hexactinellida are characterized by siliceous spicules of hexactine structure and syncytial tissue organization.

Demospongiae, the most numerous and diverse class, is a nonmonophyletic group (Boury-Esnault, 2006). They generally have a mineral skeleton made of siliceous spicules, but several lineages, like the common bath sponge, have no mineral skeleton but a network of fibers instead. Modern sponge phylogeny is now based on a combination of molecular methods and sponge morphological features, but sponge spicules are still important features for species determination and identification of sponges in the fossil record.

Sponges form one of the deepest radiations of the Metazoa and can be regarded as one of the oldest animal phylum still alive. The spicule record for sponges starts in the late Proterozoic (Reitner and Wörheide, 2002), while chemofossil records even indicate the presence of sponges – or their direct ancestors – already in the early Proterozoic: specific C₃₀ steranes (24-isopropylcholestanes), which are unambiguous biomarkers for demosponges, were found in 1,800 Ma old stromatolites (McCaffrey et al., 1994; Moldowan et al., 1994).

Choanoflagellates, a monophyletic group of protists which can show a colonial lifestyle, are the closest sister group of the Metazoa (Medina et al., 2001) and show a morphological resemblance to the flagellated choanocytes of sponges. It is, therefore, widely agreed that the “urmetazoa,” the last common ancestors of all Metazoa, would have many traits found in sponges (see review in Gaidos et al., 2007).

Numerous sponge species host vast amounts of microbes in their mesohyl matrix (Figure 1b and c) or sometimes in specialized cells, while others contain only few or no microorganisms at all. The former have been termed bacteriosponges (Reiswig, 1981) or high-microbial-abundance sponges (Hentschel et al., 2003) while the latter are referred to as “low-microbial-abundance sponges.” Bacterial population densities in bacteriosponges may reach 10⁸–10¹⁰ microbes per gram of sponge wet weight, while those in low-microbial-abundance sponges are within the range of natural seawater.

The first studies exploring the microbial community of sponges were based on electron microscopy and isolation of microbes and yielded invaluable information about the microorganism morphotypes and their specific location within the sponge (e.g., Wilkinson, 1978). Microbes were found to exist extra- and intra-cellularly (e.g., Vacelet and Donadey, 1977) and even inside the nucleus of sponge cells (Vacelet, 1970). More recently, the advent of molecular techniques have enabled a detailed phylogenetic description of the microorganisms associated with sponges (Hentschel et al., 2006), whereas environmental genomics have given insights into their metabolic and physiological properties (Grozdanov and Hentschel, 2007).

Phylogenetically complex, yet highly sponge-specific microbial communities were identified in numerous species over large geographical ranges (Hentschel et al., 2002). Sequences representing 16 bacterial phyla and both major archaeal lineages have been recovered to date (see

Sponges (Porifera) and Sponge Microbes, Figure 1 The sponge–microbe system (a) schematic representation of a sponge with microbes in the mesohyl (b) fluorescence micrograph of a DAPI stained tissue section of the sponge *Geodia barretti*, CC = choanocyte chamber, Ca = canal, Ce = sponge cells. Large DAPI signals represent nuclei of sponge cells, while small signals represent sponge microbes. Scale bar = 20 μ m (c) transmission electron microscope image of the sponge *G. barretti* showing sponge cells (lower right corner) and numerous, morphologically different sponge microbes. Scale bar = 5 μ m.

review by Taylor et al., 2007; Hentschel et al., 2003, 2006). One of these phyla, the Poribacteria, represents a new bacterial phylum, which is related to the Planctomycetales and has, so far, only been found in sponges (Fieseler et al., 2004, 2006). The other microbial phyla found in sponges are also found in other environments; however, many sponge microbes seem to form, within these phyla, monophyletic, sponge-specific 16S rRNA sequence clusters, which are absent in seawater (Taylor et al., 2007; Hentschel et al., 2003, 2006).

These recent review articles provide an excellent summary of our current knowledge about the diversity and phylogenetic affiliation of sponge microbes, and this topic will therefore not be addressed here in more detail. This article, in contrast, aims to focus on the geobiological

aspects of the sponge–microbe system: the question of a long-standing relationship between sponges and microbes; the consequences of fluctuating oxygen concentrations in sponge tissue for the sponge–microbe system; and the nature and possible function of microbial processes within sponges.

Sponge microbes: secret passengers through evolutionary history?

Did sponges and their associated microbes have an ancient partnership which remained unchanged since the origin of sponges (Precambrian), or is it a more recent but stable association which pertains to date? In an extensive review of this topic, Taylor et al. (2007) propose three scenarios which may explain the occurrence of sponge-specific

microbes. Firstly, it can be the product of a symbiosis of ancient origin perpetuated through the vertical (i.e., from adult to embryo) transmission of sponge-specific microorganisms. Secondly, the association can be the product of environmental acquisition through specific (immune system recognition, presence of favorable substrate, or bacterial protective capsule) or unspecific enrichment (rare sea-water microbes get trapped, accumulated and become thus detectable in the sponge). Finally, a combination of vertical and environmental transmissions is also possible.

The strongest evidence for a long-standing, close symbiotic relationship between sponges and some microorganisms comes from the demonstration of coevolution by comparative phylogenetic studies of sponges and their associated microbes. Erpenbeck et al. (2002) used a mitochondrial marker, cytochrome oxidase subunit 1 (CO1) and showed that the derived phylogenetic trees of four out of six symbionts were largely congruent with a tree containing sequences from the corresponding host sponges. This suggests that cospeciation had occurred (Erpenbeck et al., 2002). A subsequent study indicated a high degree of host specificity between the filamentous cyanobacterium *Oscillatoria spongelliae* and various dictyoceratid sponges (Thacker and Starnes, 2003). When comparing the phylogeny of 23 geographically, morphologically, and environmentally distant sponge species (based on their 28S rDNA gene sequences) and their associated archaea (based on 16S rDNA), a genus-specific association of these sponges with Crenarchaeota of the Marine Group I was apparent (Holmes and Blanch, 2007). These results suggest close coevolution and thus, a long-term symbiosis between these archaea and their sponge hosts. Coevolution requires that the host and symbiont maintain close association over evolutionary time. Vertical transmission, the mechanism through which coevolution could occur, has been shown for numerous sponge species belonging to all three classes of Porifera (Ereskovsky et al., 2005; Sharp et al., 2007; Schmitt et al., 2007; and references therein), including in species with highly varied reproductive strategies.

A pitfall for these comparative phylogenetic studies is that the phylogeny of sponges themselves is not yet fully resolved. This is particularly true for the Demosponges where phylogeny from the subclass to the family level is still in a state of flux (Boury-Esnault, 2006). Accordingly, our understanding of symbiont evolution in sponges will continue to develop only in parallel with improvement of our knowledge about host phylogeny. A recently initiated CO1 sequencing project for taxonomically diverse sponges (www.spongebarcoding.org) may provide data to achieve this goal in the future.

Further support for a possible ancient origin of the sponge-microbe system comes from biomarker studies. Various fatty acids of probable microbial origin occur in a wide range of sponges, irrespective of host phylogeny or geographic location (Thiel et al., 1999, 2002). The apparent absence of some of these biomarkers from

marine sediments and seawater led to the suggestion that the fatty acids and their microbial producers have been present in the sponges since ancient times.

The final type of evidence for an ancient and close association between sponges and microorganisms comes from the fossil record. Reef mounds constructed by siliceous sponges and cyanobacterial mats in the early Cambrian show that sponges and microbes closely coexisted hundreds of millions of years ago (Brunton and Dixon, 1994). Whether these microbes actually lived within the sponge tissue, as modern sponge microbes do, remains, at this stage of our knowledge, unclear.

In other words, Precambrian microorganism acquisition which started as a mere hypothesis is gaining support through studies of phylogeny, biomarkers, and fossil record. Thus, there is increasing evidence for a long-standing coevolution between sponges and certain microbial lineages, which may even date back to the roots of sponge evolution in the anaerobic, microbe-dominated world of the Proterozoic. There is evidence that a close association between sponges and bacteria may even have provided some of the genetic source material for Metazoan evolution (Lakshminarayan et al., 2004).

The alternative scenario, environmental acquisition, can, however, not be ruled out for certain sponge microbes or, in some cases, may be the more likely explanation. In this scenario, it is assumed that sponge-specific microbes are in fact also present in seawater but that our techniques fail to detect them because of their rarity. In the sponge, specific enrichment of those rare microorganisms could occur as a result of a selection through the sponge immune system (Müller and Müller, 2003) or because those microbes which possess a capsule are protected from sponge cells phagocytosis and would increase in number within the sponge body, thus becoming detectable. Unspecific enrichment is also possible and could happen through the ability of sponges to filter large amounts of water through their body. The likelihood of rare microbes being detected by our current techniques is higher in a sponge than in seawater as they might accumulate and be present in high enough numbers to be found.

The third scenario proposed by Taylor et al. (2007) is a combination of both vertical and horizontal symbiont transmissions (parental and environmental acquisition, respectively) which seems the most likely scenario to explain microbial diversity that we find in sponges today (Hentschel et al., 2002).

An anaerobic world in sponges

Until recently, sponge metabolism was viewed as being based on aerobic respiration, similarly to all Metazoa. Oxygen is usually supplied in excess to the sponge body through the water current created by the choanocytes (flagellated cells) (Reiswig, 1974). The remarkable ability of sponges to pump large amounts of water through their bodies has led to the assumption that permanent oxygen saturation exists within the sponge body. However, the

presence of anaerobic microbes in some sponge species hinted toward the presence of spatial or temporal anoxic niches (e.g., Webster et al., 2001; Hoffmann et al., 2005a; Schläppy et al., 2010a).

Gatti et al. (2002) and Schönberg et al. (2004) were the first to use microsensors to investigate the oxygen distribution in the tissue of living sponges at a microscale. Gatti et al. (2002) used oxygen micro-optodes on sponges' primorpha (multicellular aggregates composed of previously dissociated single sponge cells) and described oxygen deficiency in *Suberites domuncula*. Clark-type oxygen microelectrodes have since been used to explore the fine-scale oxygen dynamics in several sponge species from the Mediterranean and the North Atlantic. Anoxic regions have been detected in the cold-water sponge *Geodia barretti* (Hoffmann et al., 2005a) and in its explants (Hoffmann et al., 2005b), as well as in the Mediterranean sponges *Dysidea avara* (Schläppy et al., 2007) and *Chondrosia reniformis* (Figure 2) kept in aquaria or cultivation tanks with recirculating seawater.

Similarly, fluctuating oxygen concentrations leading to anoxia lasting up to 1 h were also found in *Dysidea avara* in the field when measured with an oxygen microelectrode applied by SCUBA diving (Schläppy et al., 2010a). A positive correlation between pumping activity and oxygen content was described in the tissue and in the exhaled water of *Dysidea avara* (Schläppy et al., 2007) and *Aplysina aerophoba* (Hoffmann et al., 2008). When the sponge ventilated, its body was oxygen saturated. Figure 2a shows a typical profile of a pumping sponge, with oxygen saturated water above the sponge surface and near-saturated water within the sponge tissue (compare also Hoffmann et al., 2007; Schläppy et al., 2007).

Oxygen concentrations decreased dramatically when pumping activity ceased. After 15 min without ventilation, the entire sponge body was anoxic with the exception of a 1 mm surface layer where oxygen penetrated due to molecular diffusion over the sponge surface (Hoffmann et al., 2008).

Oxygen profiles are typically diffusive over the surface and into the tissue of a nonpumping sponge (Figure 2b) (compare also Hoffmann et al., 2005b, 2008; Schläppy et al., 2007, 2010a). In situ, many sponge species reduce or even stop their pumping activity for several hours at irregular intervals (Reiswig, 1971; Vogel, 1977; Pile et al., 1997). It remains unclear whether the interruption of ventilation is caused by external events such as, for example, a high sediment load in the water (Gerodette and Flechsig, 1979; Leys et al., 1999), decrease in salinity (Fell et al., 1989), or by an intrinsic rhythm specific to a species (see Reiswig, 1971). In nonpumping sponges, molecular diffusion across a diffusive boundary layer at the sponge surface is the only source of oxygen.

The consequences of these findings are twofold. Firstly, all sponge cells and microbes which lay as deeper as 1 mm below the sponge surface need to be able to survive without direct and regular access to oxygen. Since a lack of ventilation causes tissue anoxia, the parts of the sponge

body which are not affected by surface diffusion must be alternately exposed to oxic and anoxic conditions. Secondly, by modulating the presence or absence and the magnitude of water flow through their bodies sponges have the possibility of actively switching between aerobic and anaerobic metabolism. It follows that sponge-associated microorganisms must be able to tolerate both situations and their metabolism may be activated or inactivated depending on the oxygen concentration in the sponge. This means that anaerobic microbial processes, such as sulfate reduction, for example, may take place (Hoffmann et al., 2005a; but see Schläppy et al., 2010b).

Another possible consequence of varying oxygen concentrations in sponge tissue is reported by Müller et al. (2004a, b). Using *Suberites domuncula* and its alphaproteobacterial symbiont (SB2) as a model system, they showed that the expression of genes which were essential for metabolic interaction of microbe and host was maximal under aerated conditions. Coupled with the observed loss of SB2 cells from the sponge surface under low-oxygen conditions, it was concluded that the oxygen level is responsible for regulating the bacterial fauna in *S. domuncula*. Whether this type of mechanism is equally important in other sponge-microbe systems remains to be investigated.

Tissue anoxia in sponges may act as a controlling factor toward the number of anaerobic sponge-associated microbes and act as a regulator of the nature and extent of their metabolic activity. Alternatively, it may act as a mechanism through which the sponge can kill undesirable seawater microbes. Regardless of whether anoxia in sponges is intentional or inevitable, many sponges can survive long periods of tissue anoxia and either tolerate or even foster anaerobic microbes and corresponding anaerobic microbial activity within their bodies. A close association with a diverse microbial community including (facultative) anaerobic or microaerophilic microorganisms may have been particularly advantageous at a time when fluctuating oxygen conditions were present on the Earth.

Interactions between sponges and sponge microbes

While our knowledge about phylogeny and metabolic capacities of the sponge microbes continuously increases, the role that microbes play for the sponge host is still a matter of debate. Microbes undoubtedly benefit from the nutrient-rich and protected environment of the sponge mesohyl, but the benefit to the sponge host remains unclear.

Sponge microbes may consume carbon sources which are not accessible to the sponge and may be subsequently ingested by the sponge cells. This process is commonly known as "microbial farming" and is well described (Wilkinson and Garrone, 1980; Ilan and Abelson, 1995; Vacelet et al., 1996 and own observation). Autotrophic

Sponges (Porifera) and Sponge Microbes, Figure 2 Oxygen profiles above and within *Chondrosia reniformis* showing (a) a pumping specimen with oxygen-saturated water above the sponge surface and near-saturated water within the sponge (b) a nonpumping specimen with oxygen-saturated water up to 1.5 cm above the sponge surface, a gradual decrease in the diffusive boundary layer and low oxygen concentration approaching anoxia from 2.5 cm into the sponge body. Note the different Y axes.

symbionts transform inorganic carbon (DIC) into organic carbon, which may then be transferred to the host. Energy transfer between symbiont and sponge is best described for phototrophic symbionts (e.g., cyanobacteria: Wilkinson, 1983). Chemolithotrophic processes, such as nitrification, are similar in principle. The energy which is needed for carbon fixation, however, is gained by a chemical process, the aerobic oxidation of ammonium to nitrite first and then of nitrite to nitrate. The presence of nitrifying microbes as well as the transformation of

ammonium to nitrite and nitrate have been demonstrated in many sponge species (e.g., Diaz and Ward, 1997; Diaz et al., 2004; Bayer et al., 2007; Schläppy et al., 2010b). In addition to carbon fixation, these microbes efficiently remove the sponge waste product ammonium and the toxic nitrite. Heterotrophic microbes consume simple compounds (dissolved organic carbon, DOC), while sponge cells prefer small particles such as pelagic bacteria or phytoplankton (Willenz, 1980; Pile et al., 1996; Witte et al., 1997; Ribes et al., 1999). Some sponges, however,

have been identified as important DOC sinks (Yahel et al., 2003; de Goeij et al., 2008). Interestingly, these sponges host high amount of associated bacteria. This leads to the conclusion that DOC is consumed by the sponge microbes, which in turn may be consumed by the sponge cells. A diverse community of associated microorganisms with high metabolic diversity is able to metabolize a wide array of simple molecules and to transfer them into biomass as a food resource for the sponge.

The second possibility for a mutual interaction between sponges and microbes lies within the production of secondary metabolites. Sponges produce a large variety of bioactive compounds (Blunt et al., 2003; Paul and Puglisi, 2004), which act as defenses against surface fouling, infection, or predation. Sponge microbes, which are obviously not harmed by the antimicrobial metabolites, are in fact often the actual producers of these compounds (Hildebrand et al., 2004; Piel, 2004, 2006). In addition to protecting the sponge, secondary metabolites act as a controlling factor in the host–microbe interaction.

At least some groups of sponge microbes are clearly beneficial to the sponge host, while others may be commensals.

Summary

Sponges are amongst the most ancient Metazoans on the Earth and are distributed over a wide range of aquatic ecosystems. Phylogenetically complex, yet highly sponge-specific microbial communities live in close association with numerous sponge species. A combination of both vertical and horizontal symbiont transmissions (parental and environmental acquisition, respectively) seems the most likely scenario to explain microbial diversity that we find in sponges today. Tissue anoxia is a feature found in several sponges species and is related to sponge pumping activity. Sponge microbes with autotrophic, heterotrophic, aerobic, or anaerobic metabolisms may contribute to the nutrition of the host. Other interactions between sponges and sponge microbes involve the synthesis of secondary metabolites. Due to modulation of internal oxygen concentration and the production of secondary metabolites, sponges are able to control their microbial communities. While our knowledge about the phylogeny of sponge microbes is increasing rapidly, many questions concerning the activity of sponge microbes and their interaction with the host sponge still remain unanswered. Future challenges will involve linking microbial phylogeny to microbial function on a microscale within the sponge tissue, and to examine the complex interactions within the sponge–microbe system from the origin of Metazoan life until today.

STROMATACTIS

Roman Aubrecht

Comenius University, Bratislava, Slovakia

Definition

Stromatactis is defined as a mass of spar (with partial substitution of internal sediment) which has smooth base, digitate roof, occurs in swarms and has reticulate distribution (Bathurst, 1982). Neuweiler et al. (2001) distinguished the terms “stromatactis,” “inhibited stromatactis,” and “aborted stromatactis” (Figure 1). Stromatactis originated when early internal sedimentation occurred in the open space of the cavity network followed by centripetal cementation by early marine cements in residual cavity space. Aborted stromatactis resulted from internal sediment filling of the entire or near-entire original cavity network. Inhibited stromatactis refers to incipient marine cementation of the stromatactid cavity followed by entire or near-entire internal sediment filling.

Stromatactis often (but not always) occur in mud-mounds (see entry [Mud Mounds](#)). Spar bodies similar to stromatactis but not fitting to all the points of this definition are termed in literature as “stromatactoid” or “stromatactis-like” bodies. Similar to stromatactis but smaller are fenestral pores occurring in intertidal limestones. Similar to limestones with stromatactis structures are “zebra limestones” in which the spar bodies are flat, straight, elongated, and the individual spar layers are not always interconnected.

Evolution of the term stromatactis

The term stromatactis was first used by Dupont (1881, 1882). Until present, there is still no agreement in the way of its origin. There are two main groups of opinions about the origin of stromatactis: abiogenic and biogenic. Most researchers agree that stromatactis originally represented cavities which were later filled with internal sediment and sparry calcite. The suggested abiogenic origins for stromatactis included internal erosion and reworking of small cavities (e.g., Kukal, 1971; Wallace, 1987; Bridges and Chapman, 1988; Matyszkiewicz, 1993, 1997), dewatering or escape of fluids (Heckel, 1972; Desbordes and Maurin, 1974; Bernet-Rollande et al., 1981), slumps (Schwarzacher, 1961), and freshwater karstification (Dunham, 1969). Most recent ideas involve frozen clathrate hydrates in the calcareous mud, after which the stromatactis cavities remained (Krause, 2001) or the cavities are interpreted as a result of sedimentation of stirred polydisperse sediment (Hladil, 2005; Hladil et al., 2006; Hladil et al., 2007). Some researchers supposed that stromatactis did not represent cavities and originated either by neomorphism or recrystallization of the calcareous mud (Black, 1952; Orme and Brown, 1963; Ross et al., 1975) or by dynamic metamorphism (Logan and Semeniuk, 1976). Among the opinions

Stromatactis, Figure 1 Origin of stromatactis, inhibited stromatactis and aborted stromatactis (After Neuweiler et al., 2001).

Stromatactis originated when early internal sedimentation occurred in the open space of the cavity network followed by centripetal cementation by early marine cements in residual cavity space. Aborted stromatactis resulted from internal sediment filling of the entire or near-entire original cavity network. Inhibited stromatactis refers to incipient marine cementation of the stromatactid cavity followed by entire or near-entire internal sediment filling.

favoring biogenic origin, the most widespread interpretation is that they are cavities which remained after decomposition of an unknown soft-bodied organism or by neomorphism of carbonate-secreting organism. The suggested organisms include stromatoporoids (Dupont, 1881, 1882; Lowenstam, 1950; Carozzi and Zadnik, 1959), bryozoans (Textoris and Carozzi, 1964), algae (Philcox, 1963; Textoris, 1966; Coron and Textoris, 1974), stromatolites (Cross and Klosterman, 1981), microbial colonies (Tsien, 1985), and burrowing activity of crustaceans (Shinn, 1968). The organisms that are most frequently considered to be involved in stromatactis formation are sponges. The sponge theory was first suggested by Bourque and Gignac (1983), followed by Bourque and Boulvain (1993), Neuweiler et al. (2001), and Delecat and Reitner (2005). Aubrecht et al. (2009) provided evidence that sponges were indeed involved in stromatactis

formation within Middle Jurassic mud-mound deposits. Some authors suggested an opinion that a combination of several processes played role in the onset of stromatactis, such as microbial binding of the sediment and excavating of the unbound mud (Bathurst, 1982; Pratt, 1982) or a succession of sponges and microbial colonies (Flajs and Hüssner, 1993; Flajs et al., 1996).

Stratigraphic distribution of stromatactis

Stromatactis cavities are time-dependent structures (Bosence and Bridges, 1995; Flajs and Hüssner, 1993; Neuweiler et al., 2001). The age of stromatactis cavities ranges from the Neoproterozoic (Pratt, 1995) and Cambrian (James and Gravestock, 1990), through a maximum in Devonian and Carboniferous, up to the late Jurassic (Matyszkiewicz, 1993, 1997; Jansa et al., 1989;

Pratt, 1995; Aubrecht et al., 2002). Some younger occurrences of problematic stromatactis-like cavities from the Aptian–Albian of northern Spain were reported by Pascal and Przybyla (1989), Pratt (1995), and Neuweiler et al. (1999). Even younger stromatactis-like cavities occur in Lower Albian mud-mounds of the Pyrenees (Canerot, 2001), in Turonian mud-mounds of Tunisia (Camoin and Maurin, 1988), in late Cretaceous methane-seep mounds of Tepee Buttes, USA (Kauffman et al., 1996), and in Holocene lithoherms found in the Straits of Florida (Neumann et al., 1977).

Neuweiler et al. (2001) ascribed the stratigraphic dependance and rare occurrences of stromatactis in Meso–Cenozoic sediments to the taphonomy of younger sponge taxa which was different from the Paleozoic. The post-Paleozoic taxa were prone to more rapid decay resulting in common cavity collapse and sediment filling (inhibited and aborted stromatactis).

Conclusions

Stromatactis is a mass of spar with smooth base, digitate roof, occurring in swarms, and having reticulate distribution. Various forms of stromatactis were distinguished: stromatactis, inhibited stromatactis, and aborted stromatactis, where the latter two refer to stromatactis cavities partly or completely filled by internal sediment.

There is still no agreement on how stromatactis originated. There are two main groups of opinions: abiogenic and biogenic. The theories on an abiogenic origin involved internal erosion and reworking of small cavities, dewatering or escape of fluids, slumps, dynamic metamorphism, fresh-water karstification, neomorphism, or recrystallization of the calcareous mud, frozen clathrate hydrates after which the stromatactis cavities remained, or the cavities were interpreted as a result of sedimentation of stirred polydisperse sediment. The biogenicity theories preferred the opinion that the stromatactis cavities remained after decomposition of an unknown soft-bodied organism including various hypothetical representatives, such as stromatoporoids, bryozoans, algae, stromatolites, microbial colonies, and burrowing activity of crustaceans. The most favorable are sponges for which direct evidence was found.

Stromatactis is time-dependent. Its age ranges from the Neoproterozoic and Cambrian, through a maximum in Devonian and Carboniferous, up to the late Jurassic. Some but problematic younger occurrences were found in Cretaceous and Quaternary (lithoherms in the Florida Straits). The stratigraphic dependance and rare occurrences of stromatactis in Meso–Cenozoic sediments are considered to result from the taphonomy of younger, post-Paleozoic sponge taxa.

SUBSURFACE FILAMENTOUS FABRICS

Beda A. Hofmann

Natural History Museum Bern, Bern, Switzerland

Synonyms

Moss agate p.p.; SFF; Stalactitic minerals p.p.

Definition

Subsurface filamentous fabrics (SFF, [Figures 1–5](#)) result from the encrustation of microbial filaments with minerals in subsurface geological environments, followed by oxidation of organic matter ([Hofmann, 2007](#); [Hofmann and Farmer, 2000](#); [Hofmann et al., 2008](#)). Encrustations of fibrous minerals may yield similar fabrics, but a biogenic origin is indicated by evidence for high flexibility, and a low variability of the smallest diameter of the filamentous forms, typically 1–3 μm . SFF textures vary from delicate mineral webs to massive rocks containing enclosed filaments, depending on the degree of mineral precipitation after initial filament encrustation in voids. SFF are most commonly found in voids in volcanic rocks and in the oxidation zone of ore deposits rich in reduced elements (S, Fe), but also occur in paleokarst environments ([Baele, 1998](#); [Feldmann et al., 1997](#); [Kretzschmar, 1982](#)), Mississippi Valley-type base metal deposits ([Hofmann et al., 2008](#)), cavities in fossils ([Weitschat, 1986](#)), mineral veins ([Hofmann, 1989](#); [Reitner, 2004](#); [Trewin and Knoll, 1999](#)), and cavities in impact rocks ([Hofmann et al., 2008](#)). Many of these occurrences show low-temperature hydrothermal influences. Historically, SFF have aroused the interest of researchers because of their often conspicuous nature. Examples of long-known forms are particularly the so-called moss agates, for which various interpretations have

Subsurface Filamentous Fabrics, Figure 1 Characteristic example of pseudostalactitic SFF. Encrustation of mat-like, vertically draped fabric by goethite. From the oxidation zone of a sulfide deposit, Kintore open cut, Broken Hill, New South Wales, Australia. Scale in cm.

Subsurface Filamentous Fabrics, Figure 2 SEM image of goethite-encrusted microbial filaments from the oxidation zone (in contact with glacial till) of a pyrite-rich small orebody, Lengenbach, Binntal, Switzerland. Image width: 2.9 mm.

Subsurface Filamentous Fabrics, Figure 3 Image of filamentous forms enclosed within chalcedony in a fracture within a lithophysa in Tertiary rhyolite, Priday Ranch, Oregon, USA. Image width: 4 mm.

Subsurface Filamentous Fabrics, Figure 4 Filaments encrusted by iron hydroxides, associated to numerous folded mats, and enclosed by chalcedony. Host rocks are basaltic volcanics of Jurassic/Cretaceous age. This assemblage is known as moss agate. Image width: 18 mm. Arts Bogd Uul, Mongolia.

Subsurface Filamentous Fabrics, Figure 5 Filaments encrusted by iron hydroxides, enclosed in a single quartz crystal. Paleokarst within Devonian limestones (mineralization probably of Tertiary age), Hohenlimburg, Germany. Image width: 2.8 mm.

been brought forward (Bowerbank, 1842; Daubenton, 1782; Razumovsky, 1835). Similarities do exist with some types of dendrites (present in some moss agates) and speleothems. Many examples of “stalactitic” minerals (e.g., goethite, chalcedony, chrysocolla) were formed around filamentous centers with diameters in the order of microns, much too small for true speleothems the size of which is governed by the diameter of a water droplet (Hill

and Forti, 1997). Features discriminating SFF from similar fabrics are (Hofmann et al., 2008) (a) median width of filamentous substrate of $<5\ \mu\text{m}$ with narrow, near-normal distribution; (b) evidence of bending (e.g., U-loops) and aggregation to mat-like (biofilms), stromatolite-like, or rope-like fabrics; (c) filamentous cores show a high degree of irregular bending ($>0.5^\circ/\mu\text{m}$); (d) filamentous cores show many direction changes ($>10/\text{mm}$);

(e) association of SFF with or occurrence within SFF of other morphological bioforms such as fossil *Gallionella* or *Metallogenium*-like structures; (f) presence of vertically oriented elements (may resemble stalactites) resulting from mineral encrustation of filaments, filament strands, or mats while they are still flexible; and (g) inferred environmental conditions compatible with microbial growth, such as an abundant energy source and temperatures between ambient and $<120^{\circ}\text{C}$.

Types of organisms/substrates involved: The micro-morphology of SFF indicates that only filamentous micro-organisms are involved in their formation. Filamentous substrates of microbiological origin may include archaea, bacteria, and fungi. Some fabrics formed by encrustation of mineral fibers (these may be dissolved later) may show similar morphologies, but can usually be discriminated by evidence for characteristics typical of mineral fibers: Radial growth, variable fiber thickness, straight development, brittle behavior, and remnants of mineral fibers.

Conclusions

SFF represent a common, but often overlooked, type of biosignature from subsurface environments. SFF often display macroscopically visible fabrics that are easily recognizable and may be regarded as subsurface microbialites and the most conspicuous expression of the deep biosphere, representing in some ways an analog to stromatolites from surface environments. The very common occurrence in a wide variety of different rock types demonstrates that SFF are a common expression of subsurface life, wherever filamentous forms generate a large amount of biomass in relatively short time, allowing mineralization before organic filaments are destroyed. Organisms involved were chemolithotrophs (based on oxidation of Fe, S), but may also include heterotrophs living on chemolithotrophic primary producers. The formation in subsurface environments implies that no photosynthesizing organisms are involved. SFF-like features represent a target in the search for past life on Mars (Hofmann, 2007), as they might potentially be found in nearly all rock types.

SULFATE-REDUCING BACTERIA

Heribert Cypionka
 University of Oldenburg, Oldenburg, Germany

Synonyms

Dissimilatory sulfate reducers; Sulfate-reducing prokaryotes

Definition

Sulfate reducers are prokaryotic microorganisms (Archaea or Bacteria) that use sulfate as electron acceptor of an anaerobic respiration process.

Introduction

Sulfur is one of the essential elements for life. It makes about 1% of the dry mass of living organisms and is present in two amino acids, iron sulfur clusters, and some coenzymes. Several organisms can use sulfate as sulfur source and carry out assimilatory sulfate reduction, which yields sulfide groups of amino acids. In contrast, dissimilatory sulfate reducers release large amounts of hydrogen sulfide (H_2S and HS^-) as product of their energy metabolism and cause the characteristic smell of rotten eggs. The process is carried out by a heterogeneous group of bacteria and archaea that occur in anoxic environments with temperatures up to 105°C (Widdel, 1988; Castro et al., 2000). Due to the high sulfate concentration of seawater (28 mM), sulfate reduction is especially important in marine sediments but does also occur in many other anoxic environments, e.g., lake sediments, animal guts, etc.

Evolution

The capacity of dissimilatory sulfate reduction appears to be very ancient. Its antiquity can be derived from phylogenetic analyses as well as from the geologic record (Canfield and Raiswell, 1999; Shen and Buick, 2004). Near the root of the phylogenetic tree are numerous Archaea or Bacteria metabolizing sulfur species including prokaryotes living from dissimilatory elemental sulfur reduction, dissimilatory sulfate reduction, and anoxygenic photosynthesis. As in a mixture of different isotopes of the same element lighter species are (mass-dependent) preferably metabolized by enzymes, isotope analysis of sediments can give strong evidence for their biogenic origin. The sulfur isotope distribution (^{32}S , ^{34}S , and ^{36}S) in microscopic pyrites in the ~ 3.47 billion years (Ga) old North Pole barite deposit of northwestern Australia provides the oldest evidence of microbial sulfate reduction and the earliest indication of a specific microbial metabolism. Furthermore, the observation of non-mass-dependent sulfur isotope ratios in sedimentary rocks more than 2.45 Ga old and the disappearance of this signal in younger sediments is taken as one of the strongest lines of evidence for the transition from an anoxic to an oxic atmosphere around 2.45 Ga ago (Farquhar et al., 2007).

Phylogeny

More than 120 species of sulfate-reducing prokaryotes (SRP), belonging to four bacterial and two archaeal phyla are known today (Thauer et al., 2007). The largest group are (1) mesophilic delta-proteobacteria (e.g., *Desulfovibrio*, *Desulfobacter*, *Desulfobulbus*), the other groups are (2) thermophilic Gram-negative bacteria (*Thermodesulfovibrio*), (3) *Desulfobium*, a recently established thermophilic genus not closely related to other bacteria, (4) Gram-positive bacteria with the spore-forming genus *Desulfotomaculum*, (5) Euryarcheota with the hyperthermophile *Archaeoglobus*, and (6) Crenarcheota with the hyperthermophile *Caldivirga* (Itoh et al., 1999).

Physiological groups

The most important substrates utilized by SRP are fermentation products as H_2 , alcohols, and organic acids like acetate, propionate, and butyrate. While most sulfate reducers have a limited spectrum of substrates that support growth, new isolates have been obtained that metabolize a wide variety of compounds including hexadecane, toluene, and several types of substituted aromatics (Hansen, 1994). Physiologically, sulfate reducers can be separated in two groups: Representatives of the first group generally grow fast and oxidize organic substrates incompletely to acetate, while members of the second group, grow more slowly, but oxidize their substrates completely to CO_2 . An important electron donor oxidized with sulfate as terminal electron acceptor is methane. However, so far, it has not been clarified whether sulfate reducers can oxidize methane directly or if they receive reducing equivalents in another form from an archaeal partner.

Pathway of sulfate reduction

Sulfate reduction is a rather complicated process (Figure 1). First, the double-charged anion has to be taken up by specific transport systems. Then ATP is hydrolyzed to activate sulfate to adenosine phosphosulfate (APS). This is now reduced to (bi-)sulfite, which is reduced to sulfide by sulfite reductase. APS reductase and sulfite reductase are the key enzymes. The genes coding for them (*apr* and *dsr*) are often used in molecular studies to analyze phylogeny or community structures of sulfate-reducing SRP.

Reduction of sulfate with H_2 has a ΔG_0 of -151 kJ/mol of sulfate, which is about 1/6 of the value possible with oxygen as electron acceptor. Accordingly, there is not more than 1 ATP conserved per sulfate reduced.

Alternative electron acceptors

Most sulfate reducers can utilize other sulfur compounds than sulfate, often even with a better growth yield. Sulfite is an intermediate of sulfate reduction, but does not require an energy-dependent activation. Thiosulfate can be transformed to sulfide and sulfite in a single-step catalyzed thiosulfate reductase. Some sulfate reducers can also reduce elemental sulfur. Several sulfate reducers can utilize partially reduced compounds in the absence of an electron donor: Thiosulfate, sulfite, and elemental sulfur can be disproportionated to sulfate and sulfide, and the resulting (low amount of) free energy can be used for energy conservation (Bak and Cypionka, 1987).

Furthermore, some SRP can reduce nitrate or nitrite to ammonia, some can reduce metal ions as Fe^{3+} , Mn^{4+} or even U^{6+} (Lovley, 1993), some can reduce CO_2 to acetate (homoacetogenesis), and many can grow by fermentation of simple organic molecules like pyruvate.

Several SRB have been found to reduce molecular oxygen at high rates. The process is coupled to ATP conservation. However, it appears to be a defense mechanism. Sustainable growth of sulfate reducers with O_2 as electron acceptor has never been observed (Cypionka, 2000).

Sulfate-Reducing Bacteria, Figure 1 Steps of dissimilatory sulfate reduction and chemiosmotic energy conservation with H_2 as electron donor. (1) Uptake by symport with protons, (2) ATP sulfurylase, (3) pyrophosphatase, (4) APS reductase, (5) sulfite reductase, (6) hydrogenase, (7) cytochrome c, (8) ATP synthase (Cypionka, 2006).

Summary

Sulfate-reducing prokaryotes reduce sulfate to sulfide in an anaerobic respiration process. Sulfate reduction is ancient and found in Bacteria and Archaea. The main electron donors used by sulfate reducers are fermentation products. Sulfate reduction yields little energy and proceeds via several steps. Sulfate reducers are anaerobes, although some of them are able to reduce oxygen not coupled to growth. Alternatively, other sulfur compounds, nitrate or nitrite, and some oxidized metal ions can be used by some strains.

SULFIDE MINERAL OXIDATION

D. Kirk Nordstrom

U.S. Geological Survey, Boulder, CO, USA

Synonyms

Sulfide-mineral weathering; Sulfide-ore oxidation

Definition

Sulfide mineral. A metal-sulfide compound, such as pyrite (FeS_2), which forms at high temperature ($>50^\circ\text{C}$) in well-crystallized veins or masses and at low temperatures ($<50^\circ\text{C}$) in poorly crystalline and fine-grained particles.

Oxidation. The chemical process of reacting with oxygen. More generally, the chemical process of removing electrons from an atom or group of atoms.

Introduction

Metal-sulfide minerals are valuable as ores for metals that have a wide variety of uses from jewelry to components in vehicles and electronic equipment. They are found primarily in hydrothermal mineral deposits that occur in numerous geologic environments. The most common sulfide mineral is pyrite; other important sulfide ore minerals include chalcopyrite (copper ore), molybdenite (molybdenum ore), sphalerite (zinc ore), galena (lead ore), and cinnabar (mercury ore). When these minerals are exposed to weathering at the Earth's surface, either through natural processes or as a result of mining activities, they react with oxygen in air in the presence of water to form drainage that is frequently acidic and detrimental to the environment because of the high metal concentrations. The general term for this water is acid-rock drainage. When it originates from mining activities, it is called acid-mine drainage (Nordstrom and Alpers, 1999). Acid-rock drainage is produced by numerous chemical and microbiological processes within a complex hydrogeological environment. Extensive research has been employed to understand these processes, so that mine-site remediation can be more cost-effective and long-lasting. Weathering of sulfide minerals leads to natural enrichment in copper, gold, and silver in a process known as supergene enrichment. Copper dissolves in the infiltrating water and precipitates when it reaches unweathered sulfides downgradient, enriching the original sulfides. Gold and silver are highly insoluble and are enriched in the residual iron oxide cap or gossan that forms above the unweathered ore deposit. Sulfide-mineral oxidation from both mining and natural weathering is a major source of both dissolved sulfate and dissolved metals in natural waters.

Metal extraction of primary ores and of waste piles from previous mining activities is also accomplished by hydrometallurgical techniques that have optimized sulfide-mineral oxidation by increasing the temperature of leaching, adding catalytic reagents, and bioleaching by

adding microorganisms that are specially suited for increasing the rate of sulfide-mineral oxidation.

Chemolithotrophy

Acid-mine drainage has been known since the early days of mining by ancient civilizations and was documented by early Greek and Roman writers (Nordstrom, 2009). Oxidation of sulfide minerals by microorganisms, however, has a more recent history. Winogradsky (1888) recognized that microbes could actually derive metabolic energy from the oxidation of inorganic compounds. These microbes gain energy from the oxidation (or reduction) of inorganic compounds and acquire their carbon needs from the carbon dioxide in the air (autotrophy). Hence, many of them are chemolithoautotrophs or chemoautotrophs for short. During the first quarter of the twentieth century, it was suspected that microbes affected the oxidation of sulfide minerals, but it was not until Rudolfs and Helbronner (1922) demonstrated that microbes could oxidize zinc sulfide, and Colmer and Hinkle (1947) isolated *Thiobacillus ferrooxidans*, now *Acidithiobacillus ferrooxidans*, from acid-mine drainage that microbes were recognized to be important catalysts in the production of acid-mine drainage from sulfide-mineral oxidation.

Biogeochemistry

The overall reaction of a metal sulfide like pyrite with air and water can be represented by the equation:

Pyrite + oxygen + water $\rightarrow$ acid ferrous sulfate solution.

The acidity originates from the protons needed to balance out some of the loss of electrons from iron and sulfur oxidation. The dissolved ferrous iron further oxidizes to ferric iron:

Dissolved ferric iron easily hydrolyzes and precipitates as a colloidal phase, usually a mixture of fine-grained minerals, represented by either ferric hydroxide or commonly called hydrous ferric oxide (HFO):

Dissolved ferric iron is the oxidant that directly attacks the pyrite surface so that the more correct way to write the reaction would be:

Because dissolved ferrous iron oxidizes (Equation 2) much more slowly than the oxidation of pyrite by dissolved ferric iron (Equation 4), the oxidation of pyrite

would become negligible were it not for chemolithoautotrophic microorganisms. Many types of bacteria and archaea have been found to gain energy from the oxidation of ferrous iron and reduced sulfur in acidic environments (Norris, 1990; Nordstrom and Southam, 1997; Bond et al., 2000; Ehrlich, 2002). Some bacteria, such as *Acidithiobacillus ferrooxidans*, are capable of oxidizing both ferrous iron and reduced sulfur compounds (hydrogen sulfide, elemental sulfur, thiosulfate, and tetrathionate). Other bacteria, such as *Leptospirillum ferrooxidans*, are only able to oxidize ferrous iron and some bacteria, such as *Acidithiobacillus thiooxidans*, are only capable of oxidizing reduced sulfur compounds. Iron-oxidizing archaea include *Acidianus brierleyi*, *Sulfolobus acidocaldarius* (Nordstrom and Southam, 1997), *Ferroplasma acidiphilum* (Golyshina et al., 2000), and *Ferroplasma acidarmanus* (Edwards et al., 2000). Although *Acidithiobacillus ferrooxidans* has been the subject of more studies, *Leptospirillum ferrooxidans* seems to be the more common species in acid-mine drainage (Rawlings et al., 1999; Bond et al., 2000).

The geochemistry of sulfide-mineral oxidation and its effect on surface-water quality can vary substantially depending on the composition and grain size of the sulfide minerals. Common sulfide minerals are usually either disulfides like pyrite (FeS_2) and molybdenite (MoS_2) or monosulfides like sphalerite (ZnS) and galena (PbS). Molybdenite is hydrophobic and rather insoluble so that it oxidizes and weathers very slowly whereas sphalerite is more soluble and readily reacts with acid water to produce

hydrogen-sulfide gas. The grain size of these minerals can greatly affect their oxidation and dissolution rate. The smaller the grain size, the faster they react. Hence, fine-grained crystals of pyrite can react more quickly than large crystals of sphalerite even though sphalerite would dissolve more quickly if it were the same grain size as pyrite. Marcasite has the same composition as pyrite but it reacts more rapidly because it has a different crystal structure that is more amenable to oxidative weathering.

As acid-mine drainage mixes with surface waters, the dissolved ferrous iron oxidizes and precipitates to hydrous ferric oxide (HFO) which is an excellent sorbent for trace metals. Consequently, some of the dissolved copper, lead, zinc, arsenic, and other metals will be sorbed onto colloidal particles of HFO and decrease the potential toxicity, one of several processes known as natural attenuation. This process is enhanced by the growth of masses of bacteria and algae which also sorb some of the metals, removing them from solution and decreasing the concentration transported further downstream.

Environmental consequences of sulfide mineral oxidation

Acid-mine drainage from sulfide-mineral oxidation usually discharges into streams, rivers, and lakes (Figure 1). The pH values of acid-mine drainage range from 1 to 4 although values as low as -3.5 have been measured (Nordstrom et al., 2000). The high concentrations of metals such as copper, chromium, zinc, lead, cadmium,

Sulfide Mineral Oxidation, Figure 1 Effluent from the Tinto and Santa Rosa mines flowing into the Villar River, Spain. (Photograph courtesy of Manuel Caraballo Monge, Barcelona, Spain.)

mercury, manganese, iron, and aluminum found in acid-mine drainage is too toxic for invertebrates, amphibians, fish, and other forms of aquatic or terrestrial life. Only bacteria, algae, and fungi seem to survive when the pH is about 3 or less and the concentration of metals is a few hundred parts per billion or higher. Occasionally cyanide is also released into surface waters from gold processing with harmful effects. Releases of acid-mine drainage have caused the loss of enormous quantities of fish as well as harming livestock, mammalian wildlife, and crops. Two of the largest reported spills destroyed temporarily the biological habitat of two separate river systems. One spill was from the Aznalcollar impoundment in southern Spain in April, 1998, discharging 6 million cubic meters of acid water and pyritic fines into the Guadiamar River and ruining thousands of hectares of farmland. The other spill occurred in January, 2000, releasing a hundred thousand cubic meters of cyanide and heavy metals from a 4 km impoundment at the Aurul gold extraction plant near Baia Mare in northwestern Romania. The cyanide-rich water moved down to the Lapus River, then to the Tisza River, and finally to the Danube River all the way to the Black Sea. Smaller spills from the same region occurred again over the next 2 months. Approximately, 1,200 t of fish were killed from this spill, bird life was affected, thousands of fishermen were out of work, and water supplies for several towns and rural communities were badly contaminated.

Treatment technology

Innumerable ideas have been suggested for alleviating the harmful effects of sulfide-mineral oxidation and acid-mine drainage production. These suggestions include passive wetlands treatment, bioreactors, electrochemical treatment, exchange resins, reverse osmosis, and the use of various biosolids. However, the most commonly used, safe, and cost-effective treatments today are lime–lime-stone neutralization and precipitation of the metal-rich sludge in settling ponds combined with water-management techniques. An important engineering aspect is the construction of containment structures for hazardous materials that can withstand intense rainstorms and floods and that will prevent releases into surface-water and groundwater supplies.

Conclusion

Sulfide-mineral oxidation is a complex hydrobiogeochemical process involving the oxidation of metal-sulfide minerals, catalyzed by numerous bacterial and archaeal microbial species, and producing acid-rock drainage. Mining activities enhance the rate of this process, causing the production of acidic metal-rich drainage that make receiving streams, lakes, and rivers unfit for general usage and injurious to aquatic and terrestrial biota. Major spills of mine wastes into receiving waters have severely damaged valuable aquatic resources,

farmland, community water supplies, and the economic stability of those who depend on farming and fishing. Much effort has gone into the remediation of old inactive mines and current mining activities to improve water quality for beneficial uses but the scale and complexity of the problem continues to challenge engineers and regulators.

SULFUR CYCLE

Michael E. Böttcher

Leibniz Institute for Baltic Sea Research, Warnemünde, Germany

Synonyms

Biogeochemical sulfur cycle; Sulfate reduction and sulfide oxidation; Transformation of sulfur compounds

Definition

Sulfur. Chemical element that is one of the constituents of the Earth's compartments and living organisms. While the average sulfur content of the whole Earth is about 2%, the crust contains only about 0.07% sulfur (Brimblecombe, 2003).

Sulfur cycle. Biogeochemical system of biotic and abiotic transformations of inorganic and organic sulfur-bearing components, in and between, the lithosphere, hydrosphere, atmosphere, and biosphere. Sulfur initially enters the biogeochemical cycle via volcanic activity and continental erosion. Today, the modern sulfur cycle is influenced by human activity. The Earth sulfur reservoir is assumed to have been essentially constant through time (Garrels and Lerman, 1984).

Assimilative sulfate reduction. Sulfate (SO_4^{2-}) is reduced to organic R-SH groups by plants, algae, and fungi.

Dissimilative sulfur and sulfate reduction. Hydrogen sulfide (H_2S) is produced from elemental sulfur (S^0) or dissolved sulfate by sulfur- and sulfate-reducing microorganisms, respectively. For sulfate reduction coupled to the oxidation of marine organic matter or methane, the overall reactions are:

Desulfuration. Hydrogen sulfide is produced from sulfur-containing organic molecules.

Oxidation of hydrogen sulfide. Production of sulfur intermediates, elemental sulfur, thiosulfate ($\text{S}_2\text{O}_3^{2-}$), sulfite (SO_3^{2-}), and/or sulfate by bacterial or abiotic oxidation (Jørgensen and Nelson, 2004). Possible reactions are:

Oxidation of sulfur. Sulfate is generated by the oxidation of elemental sulfur. A possible reaction is (gradient bacterium *Thioploca*):

Disproportionation of sulfur intermediates. Sulfate and hydrogen sulfide are produced by the low-temperature bacterial metabolism of sulfur intermediates. The stoichiometries of the reactions are (Finster, 2008):

In the presence of oxy(hydroxi)des of iron(III) or manganese (IV) the following stoichiometries are obtained (Böttcher and Thamdrup, 2001; Finster, 2008):

Hydrolysis of elemental sulfur. Sulfate and hydrogen sulfide can be produced by the abiotic hydrolysis of elemental sulfur at high temperatures (Smith, 2000), according to:

Formation of iron disulfide (pyrite). The low-temperature formation of iron disulfide typically takes place via the polysulfide ($\text{S}^{\circ*}$) or hydrogen sulfide pathway by the reaction with the precursor iron monosulfide (Rickard and Luther III, 2007):

The degree of pyritization (DOP) indicates the relative amount of reactive sedimentary iron that has already been reacted to pyrite.

The global sulfur cycle

The global reduced and oxidized reservoirs of sulfur, carbon, oxygen, and selected metals are coupled on different scales via redox-driven chemical, biological, and geological processes (Figures 1–4). Parts of this cycling, as the reaction between sulfuric acid (that later became popular in industrialized times as “acid rain”) and carbonate rocks, were already described in the nineteenth century by Johann Wolfgang von Goethe (Figure 1) in his famous novel “Elective affinities” (German: “Wahlverwandschaften”; published in 1809).

On Earth, pure sulfur occurs in elemental form as for example in volcanic regions, and the quantitative use of sulfur-bearing compounds by man has been used as a proxy for economic wealth (Brimblecombe, 2003). Iron sulfide sulfur occurs in almost all types of rocks and sediments and is even found in extraterrestrial meteorites. In sediments that are not under the influence of hydrothermal activity, the occurrence of sulfide sulfur is indicative for the activity of sulfate-reducing bacteria

"... Thus what we call limestone is a more or less pure calcareous earth in combination with a delicate acid, which is familiar to us in the form of a gas. Now, if we place a piece of this stone in diluted sulphuric acid, this will place a possession of the lime, and appear with it in the form of gypsum, the gaseous acid at the same time going off in vapour. Here is a case of separation; a combination arises, and we believe ourselves now justified in applying to it the words 'Elective Affinity;' it really looks as if one relation had been deliberately chosen in preference to another...."

Johann Wolfgang von Goethe 'Elective Affinity'
(*German: Wahlverwandtschaften*)

Sulfur Cycle, Figure 1 Coupling of the sulfur and carbon cycles according to Johann Wolfgang von Goethe. (Translation from Niles, 1872.)

Sulfur Cycle, Figure 2 Mass balance model of coupling between the young and old global carbon and sulfur reservoirs. (Redrawn from Berner, 1987, as a modification of the model by Garrels and Lerman, 1984.)

(e.g., Jørgensen and Kasten, 2006). Whereas sulfur is assimilated by living organisms where it is bound to, for instance, amino acids, most of the organic sulfur found in sediments is derived from early diagenetic reaction of organic matter with reduced and intermediate sulfur species (Sinninghe Damsté and de Leeuw, 1990). The decomposition of organic matter in the presence of sulfate is catalyzed by microorganisms that gain energy from the dissimilatory reduction of sulfate (e.g., *Desulfovibrio* and *Desulfobacter*; Rabus et al., 2001). Microbial oxidation of sulfide (e.g., by green and purple sulfur bacteria; gradient bacteria as *Beggiatoa* or *Thioploca*; Jørgensen

and Nelson, 2004), disproportionation (e.g., *Desulfovibrio*, *Desulfocapsa*, Finster, 2008), or further oxidation of sulfur intermediates (e.g., *Thiobacillus*) can take place aerobically or anaerobically. In the aquatic low-temperature environment, dissolved and metal-bound sulfide may also be abiotically oxidized, e.g., by manganese dioxide (Jørgensen and Nelson, 2004). The lowest oxidation state of sulfur is $-II$ (e.g., in hydrogen sulfide). In its highest oxidation state $+VI$ (e.g., in sulfate), sulfur is bound to oxygen and found as (biogenic or abiotic) barite or evaporitic sulfate minerals (e.g., gypsum or anhydrite).

Sulfur in the Atmosphere

The first atmospheric sulfur components on Earth (mainly SO_2 and H_2S) were derived from volcanic activity and may have led to the first acid rain on Earth (Farquhar et al., 2000). Volcanoes still contribute to the atmospheric sulfur budget, besides emissions from the oceans (e.g., dimethyl sulfide (DMS), carbon disulfide), coastal and wetland areas. Most of the different components temporarily end as sulfate. The anthropogenic combustion of sulfur-bearing fossil fuels in the past century not only produced CO_2 , but also led to the formation of sulfuric acid ("acid rain"), which partly led to increased rock weathering that again linked the carbon and sulfur cycles (Figure 1). In the ongoing discussion of dealing with climate change, the observations from the eruption of Mount Pinatubo are taken as an event-type base for geo-engineering concepts to decrease the global surface temperature by the artificial release of sulfur components into the stratosphere (Crutzen, 2006).

Sulfur in surface and groundwaters, and freshwater sediments

Rainwater sulfate, sulfur dioxide, and organic sulfur enter the water-unsaturated soil zone, where further

transformations take place. Geological contributions from soil and aquifer minerals vary strongly and may include gypsum dissolution and metal sulfide oxidation. Near-surface oxidation of pyrite from coal-mining activities leads today to the anthropogenically induced phenomenon of “acid mine drainage” (Holmer and Storkholm, 2001). Sulfur cycling in freshwater lake sediments associated with organic matter diagenesis is controlled by a number of factors, including temperature, light conditions, the availability of sulfate, organic matter, electron acceptors and nutrients, and macro faunal abundance (Holmer and Storkholm, 2001). Groundwater may play an important role in influencing sulfur cycling, for instance, via the

supply of evaporite-derived sulfate (Swiss Lago di Cadagno, as an example) and rock weathering (Böttcher, 1999). Sulfur cycling via organic sulfur compounds (Figure 4) plays an important role in freshwater sediments and soils (Mitchell et al., 1992; Holmer and Storkholm, 2001). Finally, sulfate may reach the ocean where further processing takes place (Figure 4).

Sulfur Cycle, Figure 6 *Upper part:* Box model for the global sulfur cycle (after: Canfield, 2004). *Lower part:* Variation of the stable sulfur isotope composition of sedimentary sulfides and coexisting seawater sulfate (from evaporites and barite). (After data from Canfield and Teske, 1996, with additions by Böttcher, unpublished data, 1998–2000.)

Sulfur in seawater and marine sediments

With a residence time of at least 8 million years, dissolved sulfate in seawater is well-mixed and reflects changes in the fluxes between and sizes of the major reservoirs (Figures 2 and 6). Whereas at mid-oceanic ridges, chemical sulfate reduction occurs in heated seawater that circulates through the Earth's crust, the low temperature dissimilatory sulfate reduction is linked to the enzymatic activity of sulfate-reducing bacteria which requires the abundance of metabolizable dissolved organic carbon compounds or methane (Jørgensen and Kasten, 2006). The anaerobic oxidation of methane associated with microbial reduction of sulfate is an important trap to prevent methane from escaping into the water column (Jørgensen and Kasten, 2006). In continental margin sediments, microbial sulfate reduction accounts for up to more than 50% of the organic matter oxidation (Skyring, 1987; Jørgensen and Kasten, 2006). Sulfate reduction may also take place in anoxic water columns (e.g., Black Sea). Most of the biogenic sulfide is reoxidized at the benthic or pelagic redoxclines by microbial or chemical processes (Jørgensen and Nelson, 2004) leading to the

metastable formation of intermediate sulfur species, or finally sulfate. The sulfur intermediates can be further oxidized, reduced, or disproportionated (Figure 4). Only a small portion of sulfide is finally buried as iron sulfides (essentially pyrite; Figure 5) or organic sulfur (Figures 2 and 4).

A number of external factors may directly or indirectly influence the rates of microbial sulfate reduction and sulfide burial efficiency, on different scales that can be reflected by the contents of sedimentary sulfur and the "reservoir" effect reflected in overall isotope discrimination (Figure 7).

Geochemical tracers for sulfur cycling: Stable sulfur and oxygen isotopes

Fractionation of stable sulfur (in dissolved and solid phase sulfur) and oxygen isotopes (in sulfate and sulfate-bearing minerals) takes place via biological and abiotic transformations and leads to isotope signatures that can be used to identify sources and biological, chemical, and physical processes involved (Canfield and Raiswell, 1999; Böttcher, 2010). Oxygen isotope fractionation can be used

Sulfur Cycle, Figure 7 Compilation of potential factors influencing availability of oxidizable organic matter available to sulfate-reducing bacteria and consequences for sulfate reduction rates and associated kinetic and reservoir size-induced sulfur isotope effect. (Modified after Ohmoto, 1992.)

to trace sulfate sources in aerobic environments (Clark and Fritz, 1997). The composition of dissolved sulfate and sedimentary diagenetic barite after modification by microbial sulfate, on the other hand, is finally governed by intracellular oxygen isotope exchange toward equilibration with surrounding water (Wortmann et al., 2007). The fossil sedimentary isotope record of pyrite (Figure 6) and anhydrite/barite/carbonate-bound sulfur, reflects the coupled changes in the atmospheric composition, the biogeochemistry of the sedimentary sulfur cycle and the fluxes between the different sulfur-bearing reservoirs (Figures 1–4 and 6) (e.g., Berner, 1987; Canfield and Teske, 1996; Canfield and Raiswell, 1999; Canfield, 2004).

Conclusion

The sulfur cycle is of general importance due to its involvement in the anaerobic mineralization of organic matter, and therefore, tight coupling to the carbon cycle. Its geochemical signature in sediments provides hints for identification of key processes associated with the evolution of life and the atmosphere on Earth. Some of the many open questions pertaining to the (bio)geochemistry and geomicrobiology of sulfur are (1) the importance of microbial versus chemical sulfide oxidation, (2) the quantitative importance of metastable intermediate and reduced sulfur species in the low-temperature sulfur cycle (Rickard and Morse, 2005; Finster, 2008), (3) the quantitative role of sulfur cycling for the deep biosphere (Jørgensen and D'Hondt, 2006), and (4) the role of metal

sulfides in extreme environments on the pre-biotic Earth for the later development of the precursors of life (Rickard and Luther III, 2007).

Synonyms

Radioactive sulfur isotopes; Stable sulfur isotopes

Definition

Sulfur. A chemical element that is one of the constituents of living organisms and of the Earth.

Isotopes. Isotopes are different nuclear forms of the same element. For a given element, a constant number of protons but different numbers of neutrons in the nucleus correspond to different isotopes. Sulfur of standard atomic mass 32.065 u has 18 isotopes, most of which are not stable and undergo radioactive decay.

Stable sulfur isotopes. Stable isotopes are isotopes that do not decay within an experimentally observable time frame. Stable isotopes have essentially the same chemical characteristics and, therefore, their behavior is chemically almost identical. The different masses lead to isotope fractionation in chemical, physical, and especially biological reactions. Four stable isotopes occur in nature: ^{32}S (95.02%), ^{33}S (0.75%), ^{34}S (4.21%), and ^{36}S (0.02%) (Hoefs, 2008). Typically, the ratio of the two most

abundant sulfur isotopes is measured and presented in the conventional δ notation as opposed to the Vienna-Canyon-Diablo-Troilite (V-CDT) standard ($\delta^{34}\text{S}$ values per mil versus the V-CDT standard). In aerobic surface environments, the sulfur isotopic composition of sulfate is often used for source identification (e.g., anthropogenic versus geogenic sulfate in rain, river, and ground waters (e.g., Clark and Fritz, 1997). Only recently has the fractionation of the minor isotopes ^{33}S and ^{36}S also been introduced into sulfur isotope biogeochemistry (e.g., Farquhar et al., 2003).

Radioactive sulfur isotopes. Sulfur has 14 unstable isotopes. Radioactive sulfur with mass 35 is formed in the atmosphere from cosmic ray spallation of argon with mass 40 and has a half-life of 87 days. Therefore, it is used in hydrological studies of biologically less active surface environments. ^{35}S -labeled sulfur compounds are used in experiments to determine microbial and chemical sulfur turnover, upon microbial dissimilatory sulfate reduction, for instance (e.g., Kallmeyer et al., 2004). The other radioactive sulfur isotopes are all short-lived.

Fractionation of stable sulfur isotopes

Sulfur isotopes are fractionated upon microbial and abiotic sulfur transformations and the isotope signal may be preserved in sedimentary sulfide- and sulfate-bearing solids, organic matter, and to a minor extent, elemental sulfur (e.g., Canfield, 2001; Amend et al., 2004). The majority of geochemical and microbial studies on sulfur isotopes have so far focused on the fractionation of ^{32}S to ^{34}S . The most important isotope discrimination step occurs during dissimilatory reduction of dissolved sulfate within the bacterial cell. The overall change in the valence state of sulfur by pure cultures leads to hydrogen sulfide that is enriched in the lighter isotope by up to about 50 per mil when compared to sulfate (Figure 1). The magnitude of isotope discrimination depends on conditions such as cellular sulfate reduction rate, substrate and sulfate concentrations, and the organisms (e.g., Kaplan and Rittenberg, 1964; Chambers and Trudinger, 1979; Bolliger et al., 2001; Canfield, 2001; Amend et al., 2004). A maximum fractionation upon sulfate reduction of up to about 70 per mil is obtained from pore water modeling in natural environments (e.g., Wortmann et al., 2001), which is close to the value predicted for thermodynamic equilibrium conditions. Further partial or complete oxidation of hydrogen sulfide is associated with only small isotope discrimination, but may lead to the formation of (metastable) sulfur intermediates. The bacterial disproportionation of these compounds (e.g., elemental sulfur, thiosulfate, sulfite) yields hydrogen sulfide that is further enriched in the lighter isotope compared with the original sulfide (Figure 1).

This may contribute to the magnitude of isotope partitioning found in shallow natural environments and the fossil record (Canfield, 2001).

Sulfur Isotopes, Figure 1 Synthesis of low temperature experimental studies on microbial and abiotic S-34/S-32 fractionations upon sulfur transformations and transport (Amrani and Aizenshtat, 2004; Böttcher and Piel, 2008; Böttcher et al., 1998; Bolliger et al., 2001; Canfield et al., 1998; Chambers and Trudinger, 1979; Cypionka et al., 1998; Fry, 2006; Habicht et al., 1998; Kaplan and Rittenberg, 1964).

Conclusions

Stable sulfur isotope partitioning preserved in the sedimentary record may serve as a proxy for microbial sulfur cycling (e.g., Amend et al., 2004; Canfield, 2001). One of the many open questions within the biogeochemistry of stable sulfur isotopes regards the conditions leading to the sulfur isotope extremes in sediments, which differ from experimental results with modern bacterial cultures. New insights are expected to derive from experiments carried out under boundary conditions that more closely approach natural environments, the consideration of new cultures, and the application of multi-isotope approaches including analysis of the minor sulfur isotopes (e.g., Farquhar et al., 2003) and sulfur-bond oxygen (e.g., Brunner et al., 2005).

SYMBIOSIS

Sharmishtha Dattagupta¹, Frank Zielinski²

¹University of Göttingen, Göttingen, Germany

²Helmholtz Centre for Environmental Research (UFZ), Leipzig, Germany

Definition

A close, prolonged physical and/or metabolic association between two or more distinct organisms.

Introduction

Most living organisms interact intimately with one or more symbiotic partners that are often vital for their health and survival. Symbiotic organisms are important ecosystem engineers (e.g., corals); they significantly impact biogeochemical cycles (e.g., legumes), and they contribute substantially to geological processes such as rock weathering (e.g., lichens and mycorrhizal fungi). Moreover, symbioses have played a crucial role in the origin and diversification of eukaryotic life.

Important terms and concepts

Symbioses are categorized as being mutualisms, where both organisms involved benefit, commensalisms, where

one organism benefits and the other remains unaffected, or parasitisms, where one organism benefits but the other is harmed. When metabolite exchange occurs between symbiotic organisms, it is called syntrophy. Syntrophic interactions among microorganisms can drive otherwise thermodynamically unfavorable reactions forward due to the removal of metabolic end products.

In symbiosis terminology, the smaller symbiotic partner (often a microbe) is referred to as the “symbiont,” whereas the larger partner is called the “host.” In ectosymbioses, the symbiont is located on the external surface of the body of its host, whereas in endosymbioses, the symbiont lives inside the body of its host, either within its cells or in extracellular spaces. Symbioses vary from being *obligate*, where the interaction is critical for the survival of at least one organism involved, or *facultative*, where the organisms involved can also survive independently of each other. The method by which the host acquires its symbionts is called the mode of transmission. In *vertical transmission*, symbionts are inherited from the previous generation, as they are passed from the parent to the egg or embryo. In *horizontal transmission*, symbionts are acquired anew in each generation either from co-occurring hosts or from the environment.

History

Symbiosis is derived from the Greek words, *syn* (together) and *bio* (life). German biologist Anton de Bary is usually credited with coining the term in the mid-nineteenth century, though an equally important contribution was made by his contemporary, Albert Bernhard Frank (who instead used the term *symbiotism*) (Sapp, 2004). De Bary introduced the term to discuss lichens, which he discovered were composites of algae and fungi. Frank, on the other hand, reported on the intimate association between fungi and roots of forest trees, which he named “mykorrhiza” (fungus root). De Bary defined symbiosis as the phenomenon in which “unlike organisms live together” and explicitly included parasitism in his definition (Kutschera and Niklas, 2005). Therefore, the original definition of symbiosis was meant to include the entire gamut of close and long-term associations between two distinct organisms, irrespective of the benefit or harm caused by the interaction. The historical definition of symbiosis was eventually replaced in many modern textbooks with a more restricted definition that included only mutually beneficial associations, making the meaning of symbiosis synonymous with “mutualism” (Wilkinson, 2001). Unfortunately, research on symbioses has been fraught with confusion and controversies, in part due to the two coexisting definitions of the term (Smith, 2001; Sapp, 2004).

Conceptually, the original definition of symbiosis makes more sense in light of the fact that “benefit” is difficult to quantify in studies of symbioses (Smith, 2001). Cost-benefit ratios of symbioses can change with environmental conditions. For example, symbiotic mycorrhizal

fungi benefit their host plants through nutrient uptake, but represent a metabolic cost to the plant under high nutrient conditions (Johnson et al., 1997). Moreover, the molecular mechanisms of communication underlying mutualistic and parasitic interactions are rather similar (Hentschel et al., 2000), and the nature of the interaction can switch during the course of evolution (Sachs and Simms, 2006). Thus, a natural continuum exists among mutualism, commensalism, and parasitism, and arguments about restricting the definition of symbiosis only serve to obscure a true understanding of the phenomenon.

Symbiosis and evolution

Symbioses can induce diverse physiological, morphological, and developmental modifications and thereby strongly influence the evolution of the organisms involved (Sapp, 2004). Microbial symbionts often confer novel metabolic capabilities to their hosts, allowing them to occupy new ecological niches. They can even alter the reproductive behavior of their hosts, and induce speciation through reproductive isolation of host populations (Engelstädter and Hurst, 2009). Conversely, the mode of transmission has a strong impact on symbiont evolution. Many vertically transmitted symbionts have severely reduced genomes, some of them retaining only limited genes corresponding to biosynthetic pathways for nutrients they provide to their host (Moran et al., 2008; McCutcheon, 2010).

Moreover, it is now commonly accepted that the rise of eukaryotes was intimately tied to symbiotic interactions. According to the “endosymbiosis hypothesis” popularized by Lynn Margulis (Margulis, 1970), mitochondria and plastids of present-day eukaryotes evolved from bacterial endosymbionts. Although the nature of the original host cell is still debated, molecular analyses have revealed that present-day mitochondria share a common ancestor with extant alpha-proteobacteria, while chloroplasts evolved from an ancient cyanobacterium (Kutschera and Niklas, 2005).

Symbiosis and its relevance to geobiology

Symbiosis research is inherently interdisciplinary in nature (Sapp, 2004), and in many cases lies at the interface between geology and biology. A few examples are given below to underscore the importance that symbioses hold for geobiologists.

Mineral weathering by symbiotic organisms

Bare rock surfaces are harsh environments for biological organisms, as they experience intense solar radiation, and strong fluctuations in temperature and humidity. Hence, cooperation rather than competition is favored, and many mutualistic or commensalistic interactions are observed in communities colonizing rock surfaces (Gorbushina, 2007). Perhaps the most well known of rock weathering agents are lichens (Fungi and Lichens). Lichens are usually considered to be symbiotic

associations of fungi and photosynthetic algae and/or cyanobacteria, but in reality they comprise complex communities of several types of microbes (Banfield et al., 1999). Lichens contribute to rock weathering through both physical and chemical processes (Chen et al., 2000). The fungal partners produce hyphae (long, branching filamentous cells) that penetrate minerals, and in combination with freeze-thaw cycles cause mineral breakdown. In addition, lichens dissolve minerals by exuding organic acids, the production of which is enhanced by symbiotic bacteria (Uroz et al., 2009). Lichens have colonized terrestrial habitats since the early Devonian (Jahren et al., 2003), and are widely distributed, occurring even in the southernmost parts of Antarctica (Chen and Blume, 2002). They can colonize and weather the same location on a rock for decades (Uroz et al., 2009), and therefore play a profound role in rock weathering.

In soil environments, mycorrhizal fungi dominate mineral weathering processes. Mycorrhizae (from the Greek *mycos* = fungus, and *rhiza* = root), which are plant-fungal associations, are the most widespread type of terrestrial symbiosis (Smith and Read, 2008). They are broadly of two types: ectomycorrhizal fungi (EMF), in which the fungal partner remains outside the plant cells, and endomycorrhiza (which includes arbuscular mycorrhizal fungi; AMF), in which part of the fungal hyphae penetrates inside the cell. EMF aggressively weather minerals by acidifying the surrounding soil microenvironment, and by exuding organic molecules that chelate metal ions (Taylor et al., 2009). They are referred to as “rock-eating fungi” as they not only dissolve surfaces of minerals but also form tunnels inside mineral grains (van Schöll et al., 2008). On the other hand, AMF indirectly enhance weathering by their plant hosts by supporting increased plant biomass and more extensive rooting systems (Taylor et al., 2009).

The role of symbiotic organisms in biogeochemical cycles

Symbiotic organisms influence biogeochemical cycles of global importance. Methane, an important green house gas, is produced in copious amounts by methanogenic symbionts of ruminants and insects (Thauer et al., 2008; Brune, 2010). In turn, Anaerobic Oxidation of Methane (AOM) in marine sediments, mediated by microbial consortia comprising intimate syntrophic associations between archaea and eubacteria, is a major biological sink of methane (Hoffmeister and Martin, 2003). AOM consortia are responsible for building massive carbonate reefs in present-day anaerobic environments such as the Black Sea and were likely important players in carbon cycling during anaerobic periods of Earth’s history (Michaelis et al., 2002). Carbonate accretion in the ocean is an important part of the global carbon cycle (Ridgwell and Zeebe, 2005), and can be enhanced by reef-building corals that depend on nutrients from their endosymbiotic dinoflagellates to maintain high calcification rates (Hoegh-Guldberg

Symbiosis, Figure 1 A wide variety of animals with chemosynthetic symbioses occur in diverse marine habitats. (From Dubilier et al., 2008, reprinted with permission from Macmillan Publishers Ltd.)

et al., 2007). Carbon cycling in Earth's history was also strongly influenced by mycorrhizal symbioses, which were intimately linked to the advent of land plants over 400 million years ago, an event that caused dramatic declines in atmospheric carbon dioxide levels (Taylor et al., 2009). Mycorrhizal symbioses also impact the global nitrogen cycle, but not as directly as nitrogen-fixing plant symbionts (Jackson et al., 2008; see entry "*Algae (Eukaryotic)*"). Bacteria belonging to the *Rhizobium* genera are often symbionts of leguminous plants, and can convert atmospheric nitrogen into ammonia, a process that has wide impact on the environment and on agriculture (Dixon and Kahn, 2004).

Geochemical influence on distribution of symbiotic organisms

Symbiotic organisms impact geological processes, and conversely, environmental geochemistry can influence the distribution and abundance of symbiotic fauna. Prime examples are chemosynthetic symbioses, which involve chemolithoautotrophic or methanotrophic microbes and invertebrate hosts (reviewed in Stewart et al., 2005; Cavanaugh et al., 2006; Dubilier et al., 2008; Petersen and Dubilier, 2009). Chemosynthetic microbes use chemical energy derived from reduced compounds such as sulfide and methane to fix inorganic carbon. The first case of a chemosynthetic symbiosis involving the giant tubeworm *Riftia pachyptila* was discovered more than 30 years ago at an eastern Pacific hydrothermal vent (see Cavanaugh et al. (2006) for details). Subsequently, chemosynthetic symbioses have been found worldwide in a large variety of marine environments including organic rich coastal sediments, Whale and Wood Falls, mud volcanoes, and Cold Seeps (Figure 1; Dubilier et al., 2008). Chemosynthetic symbioses have independently evolved multiple times, and involve at least seven different animal phyla and nine phylogenetically distinct clades of bacteria. Recently, the first case of a freshwater chemosynthetic symbiosis was discovered in a sulfur-rich limestone cave in central Italy, expanding the diversity of environments where these symbioses are found (Dattagupta et al., 2009). Since chemosynthetic microbes need to oxidize reduced compounds to derive energy, animals with chemosynthetic symbionts invariably need to bridge oxic–anoxic interfaces (Stewart et al., 2005; Cavanaugh et al., 2006). Thus, the biology and ecology of chemosynthetic symbioses are strongly interrelated with environmental geochemistry.

Summary

Symbiosis structures and influences many aspects of life on Earth. It is an important driving force in evolution, and it impacts not only the biology and ecology of organisms but also the biogeochemical processes of global importance.

SYMBIOSIS

Sharmishtha Dattagupta¹, Frank Zielinski²

¹University of Göttingen, Göttingen, Germany

²Helmholtz Centre for Environmental Research (UFZ), Leipzig, Germany

Definition

A close, prolonged physical and/or metabolic association between two or more distinct organisms.

Introduction

Most living organisms interact intimately with one or more symbiotic partners that are often vital for their health and survival. Symbiotic organisms are important ecosystem engineers (e.g., corals); they significantly impact biogeochemical cycles (e.g., legumes), and they contribute substantially to geological processes such as rock weathering (e.g., lichens and mycorrhizal fungi). Moreover, symbioses have played a crucial role in the origin and diversification of eukaryotic life.

Important terms and concepts

Symbioses are categorized as being mutualisms, where both organisms involved benefit, commensalisms, where

one organism benefits and the other remains unaffected, or parasitisms, where one organism benefits but the other is harmed. When metabolite exchange occurs between symbiotic organisms, it is called syntrophy. Syntrophic interactions among microorganisms can drive otherwise thermodynamically unfavorable reactions forward due to the removal of metabolic end products.

In symbiosis terminology, the smaller symbiotic partner (often a microbe) is referred to as the “symbiont,” whereas the larger partner is called the “host.” In ectosymbioses, the symbiont is located on the external surface of the body of its host, whereas in endosymbioses, the symbiont lives inside the body of its host, either within its cells or in extracellular spaces. Symbioses vary from being *obligate*, where the interaction is critical for the survival of at least one organism involved, or *facultative*, where the organisms involved can also survive independently of each other. The method by which the host acquires its symbionts is called the mode of transmission. In *vertical transmission*, symbionts are inherited from the previous generation, as they are passed from the parent to the egg or embryo. In *horizontal transmission*, symbionts are acquired anew in each generation either from co-occurring hosts or from the environment.

History

Symbiosis is derived from the Greek words, *syn* (together) and *bio* (life). German biologist Anton de Bary is usually credited with coining the term in the mid-nineteenth century, though an equally important contribution was made by his contemporary, Albert Bernhard Frank (who instead used the term *symbiotism*) (Sapp, 2004). De Bary introduced the term to discuss lichens, which he discovered were composites of algae and fungi. Frank, on the other hand, reported on the intimate association between fungi and roots of forest trees, which he named “mykorrhiza” (fungus root). De Bary defined symbiosis as the phenomenon in which “unlike organisms live together” and explicitly included parasitism in his definition (Kutschera and Niklas, 2005). Therefore, the original definition of symbiosis was meant to include the entire gamut of close and long-term associations between two distinct organisms, irrespective of the benefit or harm caused by the interaction. The historical definition of symbiosis was eventually replaced in many modern textbooks with a more restricted definition that included only mutually beneficial associations, making the meaning of symbiosis synonymous with “mutualism” (Wilkinson, 2001). Unfortunately, research on symbioses has been fraught with confusion and controversies, in part due to the two coexisting definitions of the term (Smith, 2001; Sapp, 2004).

Conceptually, the original definition of symbiosis makes more sense in light of the fact that “benefit” is difficult to quantify in studies of symbioses (Smith, 2001). Cost-benefit ratios of symbioses can change with environmental conditions. For example, symbiotic mycorrhizal

fungi benefit their host plants through nutrient uptake, but represent a metabolic cost to the plant under high nutrient conditions (Johnson et al., 1997). Moreover, the molecular mechanisms of communication underlying mutualistic and parasitic interactions are rather similar (Hentschel et al., 2000), and the nature of the interaction can switch during the course of evolution (Sachs and Simms, 2006). Thus, a natural continuum exists among mutualism, commensalism, and parasitism, and arguments about restricting the definition of symbiosis only serve to obscure a true understanding of the phenomenon.

Symbiosis and evolution

Symbioses can induce diverse physiological, morphological, and developmental modifications and thereby strongly influence the evolution of the organisms involved (Sapp, 2004). Microbial symbionts often confer novel metabolic capabilities to their hosts, allowing them to occupy new ecological niches. They can even alter the reproductive behavior of their hosts, and induce speciation through reproductive isolation of host populations (Engelstädter and Hurst, 2009). Conversely, the mode of transmission has a strong impact on symbiont evolution. Many vertically transmitted symbionts have severely reduced genomes, some of them retaining only limited genes corresponding to biosynthetic pathways for nutrients they provide to their host (Moran et al., 2008; McCutcheon, 2010).

Moreover, it is now commonly accepted that the rise of eukaryotes was intimately tied to symbiotic interactions. According to the “endosymbiosis hypothesis” popularized by Lynn Margulis (Margulis, 1970), mitochondria and plastids of present-day eukaryotes evolved from bacterial endosymbionts. Although the nature of the original host cell is still debated, molecular analyses have revealed that present-day mitochondria share a common ancestor with extant alpha-proteobacteria, while chloroplasts evolved from an ancient cyanobacterium (Kutschera and Niklas, 2005).

Symbiosis and its relevance to geobiology

Symbiosis research is inherently interdisciplinary in nature (Sapp, 2004), and in many cases lies at the interface between geology and biology. A few examples are given below to underscore the importance that symbioses hold for geobiologists.

Mineral weathering by symbiotic organisms

Bare rock surfaces are harsh environments for biological organisms, as they experience intense solar radiation, and strong fluctuations in temperature and humidity. Hence, cooperation rather than competition is favored, and many mutualistic or commensalistic interactions are observed in communities colonizing rock surfaces (Gorbushina, 2007). Perhaps the most well known of rock weathering agents are lichens (Fungi and Lichens). Lichens are usually considered to be symbiotic

associations of fungi and photosynthetic algae and/or cyanobacteria, but in reality they comprise complex communities of several types of microbes (Banfield et al., 1999). Lichens contribute to rock weathering through both physical and chemical processes (Chen et al., 2000). The fungal partners produce hyphae (long, branching filamentous cells) that penetrate minerals, and in combination with freeze-thaw cycles cause mineral breakdown. In addition, lichens dissolve minerals by exuding organic acids, the production of which is enhanced by symbiotic bacteria (Uroz et al., 2009). Lichens have colonized terrestrial habitats since the early Devonian (Jahren et al., 2003), and are widely distributed, occurring even in the southernmost parts of Antarctica (Chen and Blume, 2002). They can colonize and weather the same location on a rock for decades (Uroz et al., 2009), and therefore play a profound role in rock weathering.

In soil environments, mycorrhizal fungi dominate mineral weathering processes. Mycorrhizae (from the Greek *mycos* = fungus, and *rhiza* = root), which are plant-fungal associations, are the most widespread type of terrestrial symbiosis (Smith and Read, 2008). They are broadly of two types: ectomycorrhizal fungi (EMF), in which the fungal partner remains outside the plant cells, and endomycorrhiza (which includes arbuscular mycorrhizal fungi; AMF), in which part of the fungal hyphae penetrates inside the cell. EMF aggressively weather minerals by acidifying the surrounding soil microenvironment, and by exuding organic molecules that chelate metal ions (Taylor et al., 2009). They are referred to as “rock-eating fungi” as they not only dissolve surfaces of minerals but also form tunnels inside mineral grains (van Schöll et al., 2008). On the other hand, AMF indirectly enhance weathering by their plant hosts by supporting increased plant biomass and more extensive rooting systems (Taylor et al., 2009).

The role of symbiotic organisms in biogeochemical cycles

Symbiotic organisms influence biogeochemical cycles of global importance. Methane, an important green house gas, is produced in copious amounts by methanogenic symbionts of ruminants and insects (Thauer et al., 2008; Brune, 2010). In turn, Anaerobic Oxidation of Methane (AOM) in marine sediments, mediated by microbial consortia comprising intimate syntrophic associations between archaea and eubacteria, is a major biological sink of methane (Hoffmeister and Martin, 2003). AOM consortia are responsible for building massive carbonate reefs in present-day anaerobic environments such as the Black Sea and were likely important players in carbon cycling during anaerobic periods of Earth’s history (Michaelis et al., 2002). Carbonate accretion in the ocean is an important part of the global carbon cycle (Ridgwell and Zeebe, 2005), and can be enhanced by reef-building corals that depend on nutrients from their endosymbiotic dinoflagellates to maintain high calcification rates (Hoegh-Guldberg

Symbiosis, Figure 1 A wide variety of animals with chemosynthetic symbioses occur in diverse marine habitats. (From Dubilier et al., 2008, reprinted with permission from Macmillan Publishers Ltd.)

et al., 2007). Carbon cycling in Earth's history was also strongly influenced by mycorrhizal symbioses, which were intimately linked to the advent of land plants over 400 million years ago, an event that caused dramatic declines in atmospheric carbon dioxide levels (Taylor et al., 2009). Mycorrhizal symbioses also impact the global nitrogen cycle, but not as directly as nitrogen-fixing plant symbionts (Jackson et al., 2008; see entry "*Algae (Eukaryotic)*"). Bacteria belonging to the *Rhizobium* genera are often symbionts of leguminous plants, and can convert atmospheric nitrogen into ammonia, a process that has wide impact on the environment and on agriculture (Dixon and Kahn, 2004).

Geochemical influence on distribution of symbiotic organisms

Symbiotic organisms impact geological processes, and conversely, environmental geochemistry can influence the distribution and abundance of symbiotic fauna. Prime examples are chemosynthetic symbioses, which involve chemolithoautotrophic or methanotrophic microbes and invertebrate hosts (reviewed in Stewart et al., 2005; Cavanaugh et al., 2006; Dubilier et al., 2008; Petersen and Dubilier, 2009). Chemosynthetic microbes use chemical energy derived from reduced compounds such as sulfide and methane to fix inorganic carbon. The first case of a chemosynthetic symbiosis involving the giant tubeworm *Riftia pachyptila* was discovered more than 30 years ago at an eastern Pacific hydrothermal vent (see Cavanaugh et al. (2006) for details). Subsequently, chemosynthetic symbioses have been found worldwide in a large variety of marine environments including organic rich coastal sediments, Whale and Wood Falls, mud volcanoes, and Cold Seeps (Figure 1; Dubilier et al., 2008). Chemosynthetic symbioses have independently evolved multiple times, and involve at least seven different animal phyla and nine phylogenetically distinct clades of bacteria. Recently, the first case of a freshwater chemosynthetic symbiosis was discovered in a sulfur-rich limestone cave in central Italy, expanding the diversity of environments where these symbioses are found (Dattagupta et al., 2009). Since chemosynthetic microbes need to oxidize reduced compounds to derive energy, animals with chemosynthetic symbionts invariably need to bridge oxic–anoxic interfaces (Stewart et al., 2005; Cavanaugh et al., 2006). Thus, the biology and ecology of chemosynthetic symbioses are strongly interrelated with environmental geochemistry.

Summary

Symbiosis structures and influences many aspects of life on Earth. It is an important driving force in evolution, and it impacts not only the biology and ecology of organisms but also the biogeochemical processes of global importance.

DINOFLAGELLATES

Dinoflagellates are a highly diverse group of flagellated protists consisting of both photosynthetic and non-photosynthetic (heterotrophic) taxa in equal proportions (Taylor et al., 2008). Dinoflagellates are an important component of the modern plankton and have been common to abundant in marine and freshwater environments since the Mesozoic. More than 2,000 extant and 2,500 fossil species have been described. Being mostly biflagellated, swimming unicells of typically 10–100 μm in diameter, they can position themselves in the water column and take full advantage of the available light and nutrients. Many genera are indicative of (paleo-) environmental conditions such as water salinity, nutrient levels, and oceanic temperature zones. In modern and ancient sediments, dinoflagellate-derived organic matter contributions can be specified by distinctive steroid biomarkers (dinosterane and related compounds, see entry “*Biomarkers (Molecular Fossils)*”). Some dinoflagellates, called zooxanthellae, are capable of forming symbioses with a phylogenetically wide range of marine protists and invertebrate animals. For further information, see entries “*Algae (Eukaryotic)*” and “*Protozoa (Heterotroph, Eukaryotic)*.”

DIVALENT EARTH ALKALINE CATIONS IN SEAWATER

Anton Eisenhauer
IFM-GEOMAR, Christian Albrechts Universität zu Kiel,
Kiel, Germany

Synonyms

Divalent cations in seawater

Definition

The most abundant divalent earth alkaline cations in seawater are Mg^{2+} , Ca^{2+} , and Sr^{2+} are simply termed the “divalent cations.” These ions and their dynamic change play a major role for the modern oceans. On long geological time scales dynamic changes of divalent cation concentrations in the oceans influenced the evolution of life and the climate evolution in the past.

Divalent cations in modern ocean water

Magnesium

Magnesium is a chemical element with the symbol *Mg*, the atomic number 12, and an atomic mass of 24.31.

Magnesium is the ninth most abundant element in the universe by mass. It constitutes about 2% of the Earth’s crust by mass, and it is the third most abundant element dissolved in seawater and it is the most abundant divalent cation followed by Ca and Sr in seawater (Brown et al., 1992). Mg ions are essential to all living cells, and is the 11th most abundant element by mass in the human body. In seawater ($S = 35$ psu), Mg is present at approximately 53 mM (mM = millimolar) (Brown et al., 1992). Only the monovalent sodium (Na^+ , 469 mM) is present at higher concentration. Magnesium is about five times more abundant than the third most abundant cation Ca (10 mM). Magnesium concentration is significantly lighter than calcium, so when compared on a weight basis, it is only about 3 times as concentrated (1285 vs. 420 ppm). Magnesium is present in seawater as a free divalent cation with water and other molecules attached to it (Brown et al., 1992; Kastner, 1999). It is estimated that each Mg^{2+} ion has approximately eight water molecules (ligands) tightly bound to it. A small portion (about 10%) of the magnesium is present as a soluble ion pair with sulfate (MgSO_4), and much smaller portions are paired with bicarbonate (MgHCO_3^+), carbonate (MgCO_3), fluoride (MgF^+), borate ($\text{MgB}(\text{OH})_4^+$), and hydroxide (MgOH^+).

While these ion pairs comprise only a small portion of the total magnesium concentration, they influence seawater chemistry to a large extent. In the case of carbonate (CO_3^{2-}), for example, the ion pairing to magnesium stabilizes the carbonate that it is present in far higher concentrations than it would be present in the absence of magnesium. This effect makes seawater a much better buffer in the pH range of 8.0 than it otherwise would be. Without this ion pairing, seawater pH might be significantly higher, and more susceptible to dynamic changes. The average residence time for a magnesium ion in seawater is on the order of several tens of millions of years. That time is substantially longer than that for Ca (~one million years) and aluminum (Al, 100 years), but less than Na (~250 million years). The long seawater residence time of Mg in seawater is a measure of its fairly unreactive chemical behavior indicating that it does get taken out of solution through various biological and chemical processes.

Sources and sinks for magnesium in the oceans

In the present-day ocean, the two most important calciumcarbonate (CaCO_3) polymorphs – low Mg-calcite and aragonite – are the most prevalent carbonates and major sinks for Mg replacing Ca to some extent in the crystal lattice. Mg also precipitates together with Ca directly from the water in some evaporitic settings, as well as by the dissolution and reprecipitation of calcite with magnesium replacing calcium in the crystal structure. Dolomite, a high magnesium type of calciumcarbonate usually does not form in the well-oxygenated modern oceans, although bacterial alteration of seawater is reported to induce dolomite precipitation (Kastner, 1999; McKenzie, 1981) in certain marine anoxic environments.

shortly after the extreme glaciations during the late Neoproterozoic (Hoffman et al., 1998) and was nearly synchronous with the rapid evolutionary pulse that coincides with the Ediacaran and Cambrian radiations. Final assembly of Gondwanaland and a circum-Gondwanaland mountain chain is thought to have provided nutrients to the oceanic realm and also resulted in a large $^{87}\text{Sr}/^{86}\text{Sr}$ spike due to the erosion of the mountains (Squire et al., 2006). Therefore, links between the assembly of the Gondwanaland supercontinent and biological evolution are forwarded by numerous studies (Meert and Lieberman, 2008).

GREAT OXYGENATION EVENT (GOE)

The term “Great Oxygenation Event” (GOE, also known as “Great Oxidation Event,” “oxygen catastrophe,” or “oxygen crisis”) describes a critical environmental change in Earth history that resulted from the appearance of diatomic oxygen (O_2), a waste product of oxygenic photosynthesis, in the atmosphere. The GOE occurred around 2.4 billion years (Ga) before present, close to the boundary between the Archean and the Proterozoic (2.5 Ga). For details, please refer to “[Critical Intervals in Earth History](#).”

GREEN ALGAE

Green algae are photosynthetic eukaryotes with simple plastids (derived from primary endosymbiosis) that are mostly microscopic and rarely more than a meter in greatest dimension. The approximate 6,000 extant species show an enormous diversity of growth habit and fine details of their cellular architecture. Green algae occur as unicellular or colonial, microscopic or macroscopic, motile planktonic, as well as benthic attached forms. Some (e.g., Dasycladales) are important carbonate producers in aquatic environments, others live in symbiotic associations with fungi to form lichens in terrestrial settings. Green algae living as endosymbionts inside heterotrophic organisms are a common phenomenon. The order Charales, in which full tissue differentiation occurs, is considered to include the closest relative of higher plants. For details, please refer to entry “[Algae \(Eukaryotic\)](#).”

GUILD

Metabolically related populations, e.g., sulfate-reducing microorganisms. See entry “[Microbial Communities, Structure, and Function](#)” for further reading.

GEYSERITE

A dense, banded or laminated variety of sinter that forms at and near the vents of geysers and some hot springs. See entries "[Sinter](#)" and "[Hot Springs and Geysers](#)" for further reading.

GLASS

See entry "[Basalt \(Glass, Endoliths\)](#)."

GLAUCOPHYTES

Glaucoephytes (glaucoecystophytes or glaucoecystids) are colorless freshwater protists containing plastids derived from primary endosymbiosis (see also entry [Symbiosis](#)) that is, they are still surrounded by a peptidoglycane wall, which may be viewed as reminiscent of their cyanobacterial origin. Previously, these primitive plastids were also called "cyanelles." For details, please refer to entry "[Algae \(Eukaryotic\)](#)."

GOLD

Veit-Enno Hoffmann
University of Göttingen, Göttingen, Germany

Synonyms

Aurum (Latin)

Definition

Precipitation/Bioaccumulation of gold is the precipitation of fine-grained gold colloids by microbial activities.

Nugget. A natural gold grain (>5 mm, >200 mg).

The impact of the use of microbial activity for the solution and precipitation of gold was undervalued for a long period, thus affording the opportunity for economic and environmentally friendly gold bio-processing. Furthermore, the current high price of gold has led to intensive research into the precipitation of gold.

Some iron and sulfur oxidizers (e.g., *Acidothiobacillus ferrooxidans*, *Acidithiobacillus thiooxidans*) contribute to the disintegration of important gold ores (Nordstrom and Southam, 1997). In an environment of gold-bearing rocks, the dissolved gold content is 40 times higher than in comparable non-gold-bearing areas (Benedetti and Boulègue,

1991). It has been shown that the dissolution of gold is dominated by the gold thiosulfate complex $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ which is composed of the above-mentioned bacteria and Actinomycetes (e.g., *Streptomyces fradiae*) (Nordstrom and Southam, 1997; Sand et al., 2001). However, $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ is only stable until the sulfur-oxidation is complete (Lengke and Southam, 2005). Subsequently the gold thiosulfate complex is degraded by *A. thiooxidans*. Thereby gold accumulates in the form of fine-grained colloids inside the bacterial cell and on the surface of the cell membrane. Comparable with the results of Southam and Beveridge (1996) with *Bacillus subtilis* 168, hexagonal-octahedral gold crystals are generated out of the colloids after some months (Figure 1).

As a result of the toxicity of an increasing content of ionized gold, most of the microorganisms that can generate gold die on accumulation of gold. However, various microorganisms, such as bacteria (e.g., *Escherichia coli*, *Pseudomonas maltophilia*, *Plectonema boryanum*), Archaea (e.g., *Pyrococcus furiosus*), Actinomycetes (e.g., *Streptomyces cinamonensis*), fungi (e.g., *Neurospora sitophila*, *Fusarium oxysporum*) and yeasts (e.g., *Endomycopsis fibuligera*, *Sporobolomyces salmonicolor*) from different environments (e.g., hydrothermal, supergene), are partially resistant to the toxicity induced by the accumulation of gold (Kashefi et al., 2001; Nakajima, 2003; Lengke et al., 2006). These bioaccumulation processes are related to various microbial activities (e.g., detoxification, energy generation, passive adsorption). In the laboratory, *Pseudomonas aeruginosa* biofilms demonstrate a higher resistance to the toxicity of gold than planktonic *P. aeruginosa* cells and form solid gold at the base of the biofilms (Karthikeyan and Beveridge, 2002). Reith et al. (2006) isolated a 16SrDNA sequence from natural samples. This sequence was only found on gold grains

Gold, Figure 1 A secondary electron (SE) image of a hexagonal gold crystal from the secondary gold deposit Silberkuhle near Korbach, Germany.

REMINERALIZATION (OF ORGANIC MATTER)

Degradation of organic matter that results in net conversion of organic carbon to inorganic (oxidized) carbon species such as CO_2 or HCO_3^- . See entries "[Carbon \(Organic, Cycling\)](#)" and "[Carbon \(Organic, Degradation\)](#)" for further reading.

RHODOPHYTA

The Rhodophyta, also referred to as "red algae," are a distinct eukaryotic lineage of algae with simple plastids (two membranes, derived from primary endosymbiosis). Rhodophytes have a long geological record since the Mesoproterozoic (1.2 Ga). Today, they encompass about 670 largely marine genera with up to 4,500 species predominating the coastal and continental shelf areas of tropical, temperate, and cold-water regions. Red algae are significant as primary producers and providers of structural habitat for other marine organisms. Calcifying (coralline) red algae play an important role in the primary establishment and maintenance of limestone reefs. For further details, see entry "[Algae \(Eukaryotic\)](#)."

RNA-WORLD

The term "RNA-World," first suggested by Walter Gilbert in 1986, describes a popular concept on a hypothetical early stage in the origin of life on Earth. Based on discoveries of enzymatic activities in microbial ribonucleic acids (RNA), a system was suggested where primordial RNA molecules accounted for both, the storage of genetic information and catalytic functions necessary to assemble themselves in a primitive self-replicating system. The RNA molecules evolved in self-replicating patterns, using recombination and mutation to explore new functions and to adapt to new niches (Gilbert, 1986). Such a system would not have required the presence of DNA and/or protein enzymes for biochemical reactions. For further reading, please refer to "[Origin of Life](#)."

HAPTOPHYTES

Haptophytes (Haptophyta, Prymnesiophyta) are unicellular chlorophyll a and c containing algae with complex plastids derived from secondary endosymbiosis (“red lineage”) (see entry “*Symbiosis*”). They occur principally as solitary free-living motile cells that possess two smooth flagella, unequal in length in the Pavlovophyceae and more or less equal in the Prymnesiophyceae. Haptophytes inhabit littoral, coastal, and oceanic waters and are important primary producers in many aquatic environments. Within the haptophytes, the so-called coccolithophores (coccolithophorids) evolved the ability to control the intracellular calcification onto organic plates and the assembly of the mature calcium carbonate (calcite) scales (coccoliths) at the cell surface. These forms have been significantly contributing to the deposition of calcium carbonate in marine waters since the Mesozoic, today accounting for about a third of the total marine CaCO₃ production. In modern and ancient sediments, haptophyte-derived organic matter contributions can be specified by distinctive lipid biomarkers (alkenones), whose unsaturation patterns also provide a paleo-thermometer for past surface water temperatures (see entry “*Biomarkers (Molecular Fossils)*”). For further details, please see entry “*Algae (Eukaryotic)*.”

HISTOLOGY

Michael Gudo¹, Gerta Fleissner², Guenther Fleissner²

¹Morphisto Evolutionsforschung und Anwendung GmbH, Institut für Evolutionswissenschaften, Frankfurt am Main, Germany

²Goethe-University Frankfurt, Frankfurt a. M., Germany

Definition

Histology is the biological science concerned with the minute or microscopic structures of cells, tissues, and organs of animals, plants, and fungi, in relation to their function, and any organismic constructions produced by living individuals or symbiotic assemblies of living organisms.

Biopsy is the sample of an organism or part of a tissue that is processed for histological investigations.

Fixation serves the inhibition of all vital processes by special chemicals that also preserve and prepare organic matter for further histological or morphological investigations.

Mineralization is the process by which organic components of organisms are impregnated or replaced by inorganic material and converted to mineral matter.

Staining is the chemical reaction of particular laboratory chemicals (stains and dyes) with tissue components and materials of the samples.

Introduction

The term histology was coined by C. Mayer in 1819 as a part of the scientific discipline comparative anatomy (Mayer, 1819). Histological investigations, concerned with the minute structures of cells, cell organelles, intra- and extracellular fiber arrangements, and tissue components and organs in relation to their function, are usually done by light microscopy. Since the invention of the microscope by Leeuwenhoek in 1668 (Palm and Snelders, 1983), the early histological technology (Gerlach, 1998) has experienced major improvement by the refinement of microscopes (Bozzola and Russell, 1999) and new methods of tissue preservation, sectioning devices, stains, and staining methods. Histochemical methods now permit to identify and localize intracellular components and enzymes within distinct and isolated samples (e.g., Bancroft and Gamble, 2007; Böck, 1989; Horobin and Kiernan, 2002; Mulisch and Welsch, 2010). Therefore, the studied structures, tissues, complete organisms, or any organismic compound have to be preserved from enzymatic decay, and then cut into sections of just a few microns thickness. The histological sections can vary between ultra thin sections (40–80 nm), semi thin sections (0.1–3.0 µm), thin sections (3–20 µm), and thick sections (more than 20 µm). While ultra thin sections could be investigated only by transmission or scanning electron microscopy (TEM), the others can be investigated with any light microscope. Afterward, these sections are

ACIDOPHILES

“Acidophiles” are organisms thriving in environments below pH 5. For details, see entries “*Extreme Environments*,” “*Biomining (Mineral Bioleaching, Mineral Biooxidation)*,” “*Hot Springs and Geysers*,” *Hydrothermal Environments (Marine)* and “*Acid Rock Drainage*.”

ACRITARCHS

Acritarchs are organic-walled acid-resistant microfossils known from the Proterozoic and throughout the Phanerozoic. The position of these microfossils is still uncertain. A number of acritarch genera have been assigned to Green Algae; others are considered to bear some resemblance to the cysts of dinoflagellates. For more information, please refer to entries “Algae, Eukaryotic” and “Protozoa.”

AEROBIC METABOLISM

Heribert Cypionka
University of Oldenburg, Oldenburg, Germany

Synonyms

Aerobic respiration; Oxygen metabolism

Definition

Aerobic metabolism comprises the reduction of molecular oxygen as electron acceptor of aerobic respiration, its use as cosubstrate in the degradation of certain compounds, and reactions leading to the detoxification of partially reduced oxygen species.

Introduction

Life has evolved in the absence of molecular oxygen (see Chapter *Early Earth*). Therefore, it is not surprising that basic metabolic pathways involved in growth and cell division (like DNA replication or protein synthesis) do not depend on the presence of molecular O₂. The evolution of the oxygen-producing (oxygenic) phototrophs dramatically changed the situation of living organisms. Molecular oxygen raised the redox potential of the environment and enabled microorganisms to respire with a much higher energy yield than before. Although oxygen is involved in

a limited number of reactions only, its presence or absence has fundamental impact on biogeochemical processes.

Aerobic degradation of organic matter

Aerobic respiration consumes a major part of the photosynthetically produced O₂ and about 90% of the organic matter (see Chapter *Carbon Cycle*). Aerobic (oxygen-metabolizing) organisms normally oxidize their substrates completely to CO₂. In most cases, O₂ is not directly involved in this process. Substrate oxidation generates reduced electron carriers by means of the respiratory chain. Oxygen is reduced as the last step of the respiration process.

Respiratory chain

Respiration is a membrane-bound process that generates a chemiosmotic proton gradient across the membrane (Mitchell, 1966). Respiratory chains are composed of series of enzymes, which are organized in multienzyme complexes and use cofactors that allow the stepwise transport of reducing equivalents to oxygen (Figure 1). In eukaryotes (plants, animals, fungi) it takes place within the mitochondria, which are assumed to have evolved from endosymbiotic bacteria. In prokaryotes (Bacteria, Archaea), the respiratory chain is located in the cytoplasmic membrane. The respiratory chain of the bacterium *Paracoccus denitrificans* appears to have many similarities to the mitochondrial type (Harold, 1986). However, many bacteria have variations compared to the mitochondrial type presented in Figure 1.

Energetics and ATP conservation

Most reducing equivalents are fed into the respiration process via NADH₂, which has a standard redox potential (E_0') of -0.32 V. The terminal electron-accepting redox pair O₂/H₂O has redox potential of $+0.82$ V. Thus, the usable redox potential is about 1.14 V. From this redox potential one can calculate a standard $\Delta G_0'$ of -440 kJ per mol of O₂. Assuming that ATP conservation requires about -75 kJ per mol, the conservation of 5 to 6 ATP per O₂ reduced is possible. As a consequence of the high ATP yield, aerobic organisms can form more biomass from the same amount of substrate than anaerobic organisms.

Use of oxygen as cosubstrate

Molecular oxygen is used as a cosubstrate in some catabolic and anabolic reactions (Lengeler et al., 1999). The enzymes involved are called mono- or di-oxygenases, depending on the number of oxygen atoms transferred to their substrate. Oxygenases are used by aerobes to activate certain substrates that do not have functional groups that allow a simple degradation. They catalyze the initial hydroxylation of hydrocarbons to yield alcohols that can easily be metabolized further. They are also involved in the ring cleavage of aromatic compounds and in the first oxidation step of ammonia oxydation. Anaerobic organisms are either unable to oxidize the substrates activated

C

CALCAREOUS ALGAE

The term “calcareous algae” refers to various kinds of benthic and planktonic algae whose thalli contain biochemically precipitated calcium carbonate (CaCO_3) as skeletal material (Wray, 1977; Braga and Riding, 2005). Precipitation of CaCO_3 (as calcite and/or aragonite) may occur within or on the algal bodies. The term may also include mechanically accreted deposits of calcium carbonate caused by algae, usually as an interaction of biological and physical processes. Calcareous algae are a highly artificial group that constitutes calcifying members of the Chlorophyta (green algae), Rhodophyta (red algae), and Phaeophyta (brown algae) and is sometimes also used for Cyanobacteria. At present, calcareous algae are one of the most important reef builders (see “[Carbonate Environments](#)”). For a detailed reading, please refer to “[Algae \(Eukaryotic\)](#).”

CALCIFIED CYANOBACTERIA

Robert Riding
University of Tennessee, Knoxville, TN, USA

Definition

Cyanobacteria are alga-like bacteria that can perform oxygenic photosynthesis and nitrogen fixation (Whitton and Potts, 2000; Herrero and Flores, 2008). They have a long history and are diverse and widespread in marine, freshwater, and terrestrial environments at the present-day, where they are key primary producers in both microbial mat and planktic ecosystems. As the initiators of plastids, they have played a fundamental role in algal and plant evolution (Raven, 2002). Cyanobacteria occupy benthic substrates and can also drift in the water column. Their photosynthetic uptake of inorganic carbon can stimulate CaCO_3 precipitation. This calcification can produce filamentous microfossils in benthic mats that are preserved as stromatolites and thrombolites, and can also cause water column precipitation of carbonate mud that settles to lake and sea floors.

Introduction

However, cyanobacterial calcification is not obligatory and is directly dependent on environmental conditions. This accounts for apparent discrepancies between the geological ranges of organic-walled and calcified cyanobacterial fossils. Calcified cyanobacteria have not been recognized in marine sediments older than ~1200 Ma ago (Kah and Riding, 2007), whereas there is evidence that cyanobacteria appeared in the late Archaean or Palaeoproterozoic, in the range ~2900–2150 Ma ago (Cavalier-Smith et al., 2006; Hofmann, 1976). This mid-Proterozoic appearance of sheath-calcified cyanobacteria is thought to reflect the development of CO_2 -concentrating

SILICOFLAGELLATES

Silicoflagellates are planktonic, microscopic algae with siliceous skeletons, characterized by their simple geometries and remarkable variability. Taxonomically, they belong to different classes of the Stramenopiles and possess complex plastids derived from secondary endosymbiosis (see entry [Symbiosis](#)). Silicoflagellate skeletons may have considerable potential as environmental indicators and are common in fossil deposits, dating back to the middle Cretaceous (ca. 120 Ma), with species diversity reaching a peak in the Miocene (ca. 23–25 Ma). Today, only a single genus *Dictyocha* with approximately five recognized species exists. For more details, please refer to entry ["Algae \(Eukaryotic\)"](#).

PEDOGENIC CARBONATES

Eric P. Verrecchia
Université de Lausanne, Lausanne, Switzerland

Synonyms

Secondary terrestrial carbonates; Soil carbonates; Vadose zone carbonates

Definition

Definition and mineralogy

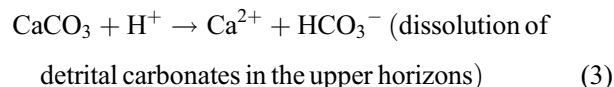

Pedogenic carbonates are authigenic (or secondary) carbonate deposits precipitated in soils (Lal et al., 2000). When found in the soil but directly inherited from parent materials, carbonates are defined as detrital or lithogenic (Kraimer et al., 2005). Pedogenic carbonates are characterized by a wide diversity of shapes, from secondary diffuse micritic (micron-size) crystals inside the soil matrix to coalescent hardened layers, sometimes capping whole landscapes. They are mainly composed of calcium carbonate as calcite and rarely as aragonite (Schaetzl and Anderson, 2005), of magnesian calcite, dolomite (Whipkey et al., 2002), and occasionally of iron-rich carbonate such as ferroan calcite, siderite, and ankerite (Table 1). Iron-rich carbonates are generally found in organic-rich soils and soils under the influence of

water-table fluctuations with active oxidation–reduction processes.

Origin

Carbonate physicochemical equilibria

Various processes are involved in pedogenic carbonate formation. The first significant process is related to the leaching of carbonate through the soil profile. In the upper horizons, inherited calcium carbonate is dissolved by carbon dioxide enriched waters and displaced in solution toward deeper horizons where it precipitates. This precipitation is supposed to occur if the concentration in Ca^{2+} increases, the pCO_2 decreases, or if soil solutions concentrate due to water loss (evaporation). In other words, all these processes are driven by the following general equations when lithogenic (detrital) carbonates are involved:

A second process is related to the transformation, in surficial environments, of primary minerals which can also lead to the precipitation of pedogenic carbonates. For

COSMIC MOLECULAR CLOUDS

Joachim Reitner

University of Göttingen, Göttingen, Germany

Synonyms

Complex molecular clouds; Interstellar clouds; Interstellar dust and molecules; Molecular clouds

Definition

A cosmic molecular cloud is an accumulation of cosmic matter that is composed of organic and inorganic molecules. The dust grains in a cosmic molecular cloud are mainly composed of crystalline silicates (Watson et al., 2009) covered with ice of H_2O , NH_3 , and CO_2 . The main molecule constituent is H_2 -He, but other molecules also occur, e.g., NH_3 , CO , and complex organic molecules.

Cosmic molecular clouds are denser than the interstellar medium, with gas densities ranging from about 10 molecules per cm^3 on large scales to over 10^6 molecules per cm^3 in cloud cores. These cores are very cold, with temperatures ranging from 8 to 20 K. New stars and protoplanetary discs are formed, when it comes to a gravitational collapse of cosmic molecular clouds. Via nucleosynthesis, these stars produce elements, which may constitute organic molecules (e.g., H, C, N, O, S, P). When

stars burn out, they collapse either via catastrophic explosions or by forming expanding shells, thereby recycling modified material back into the interstellar space and, thus, forming new cosmic molecular clouds (Boss, 2004). Some of the interstellar clouds are enriched in prebiotic organic molecules. These molecules are found in cosmic matter, chondritic asteroids/meteorites, and cosmic dust particles.

Based on spectroscopic wavelength analyses, more than 120 different complex organic molecules could be detected within cosmic molecular clouds, including common PAHs (polycyclic aromatic hydrocarbons), amino acids, sugars ("polyols"), hydrogen cyanide (HCN), and formic acid (Figure 1) (Ehrenfreund and Menten, 2001). The largest organic molecules so far reported from cosmic molecular clouds are cyanodecapentayne (HC_{11}N) and diethyl ether ($\text{C}_2\text{H}_5)_2\text{O}$. Not all of these molecules are part of the gaseous phase, but the more complex ones are related with cosmic dust particles. A well studied cosmic molecular cloud is the Sagittarius B cloud, where the most complex organic molecules like ethyl cyanide, acetone, glycine, acetic acid, and glycolaldehyde were detected (Hollis et al., 2000; Snyder, 1997). Glycolaldehyde may react with ribose to form a molecule, which is a major constituent of RNA. It was hypothesized that organic molecules within a cosmic molecular cloud are formed on 1–2 μm -sized dust grains, e.g., via photochemical reactions. These dust grains have a distinctive shell-like structure. An inner core of silicates is covered by an inner rim

Cosmic Molecular Clouds, Figure 1 Interstellar space with the occurrence of different organic molecules. (From Ehrenfreund and Charnley, 2000.)

containing complex organic compounds like amino acids, “polyols,” and carbonaceous matter such as hydrogenated amorphous carbon or kerogen-like material. The inner rim is covered by an outer rim consisting of “dirty” ice. In that icy outer rim, due to the heavy ultraviolet radiation, radicals are formed and H_2 is dissociated in monoatomic H that may react with other radicals to form organic molecules (Sorrell, 2001; Pearson et al., 2002). An important finding obtained with the Hubble Space Telescope was the observation of protoplanetary discs in the Orion cloud (Megeath et al., 2005). The size of these discs is more or less similar to our solar system. During solar system formation, an interstellar cloud becomes the building block, from which planets, asteroids, and comets form. Comets and carbonaceous chondrites are chemically very similar to star-forming interstellar clouds and are relics of them (Busemann et al., 2006; Wickramasinghe et al., 2009). They carry pristine primitive organic matter and represent a plausible source of prebiotic organic matter on the late Hadean early Earth. The stable isotope compositions of organic matter, e.g., from the Murchison carbonaceous chondrite (CM2), provide clear evidence that the organic matter was formed under conditions in stellar clouds and not on Earth (Sephton et al., 2003, see entry “*Meteoritics*” for further reading). External delivery of water and organic compounds is widely accepted as the origin of pristine earth-related organic matter (Wickramasinghe, 2010) and may have pushed the start of early life with the first microbial organism – *LUCA* – *Last Universal Common Ancestor* (Hoenigsberg, 2003).

CRITICAL INTERVALS IN EARTH HISTORY

Frank Wiese, Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

In our human understandings of time, Darwinian evolution is something, which happens very slowly. Consulting the (biogeochemical) fossil record, we notice periods in life’s history, which are characterized by slow and continuous evolution, successive background extinction, and equally successive new speciations. On the other hand, we see also periods, during which a sudden occurrence of new groups and its rapid radiation and dispersal can be seen in the fossil record. *Vice versa*, we also recognize catastrophic extinction events (mass extinctions; see below), reducing the number of known taxa dramatically within a very short time of only thousands of years or even much less.

Among these intervals were phases, in which comparatively short-termed (in a geological sense) pulses of evolution resulted in significant and irreversible evolutionary innovations, which opened new paleobiological pathways, affecting the abiotic and biotic evolutionary landscape likewise. These intervals are what we understand as main critical intervals in earth’s history here, and we believe that three periods merit this designation. These are the

(Dobbek et al., 2001; Voordouw, 2002). The Ni-containing CODH is involved in many reactions in anaerobic microorganisms: it catalyzes the oxidation of CO with H₂O to CO₂ and H₂ in carboxydophilic bacteria, and assists the oxidation of acetate to CO₂ in sulfate-reducing bacteria and archaea and the disproportionation of acetate to CH₄ and CO₂ in methanogenic archaea. In many groups of anaerobic microorganisms utilizing the reductive acetyl-CoA pathway, such as acetogenic bacteria or methanogenic archaea, CODH is often found in a complex with ACS (Strauss and Fuchs, 1993; Holo and Sirevag, 1986; Drennan et al., 2004). ACS catalyzes the formation of acetyl-CoA from CO, leading in combination with the CODH to the synthesis of acetate from two CO₂. These two enzymes play an important role in the global carbon cycle, since up to 10% of the organic carbon produced by photosynthesis is remineralized by anaerobic microorganisms involving CODH/ACS (Drake, 1994). MCR is the key enzyme of methanogenic archaea catalyzing the final step during the reduction of carbon dioxide to methane (Thauer, 1998). All biologically formed methane is produced by methanogenic organisms in the terminal step of anaerobic degradation. The nickel is located in a tetrapyrrole coenzyme named F₄₃₀, which is unique to methanogenic archaea. MCR catalyzes the reduction of methyl-coenzyme M with a reduced coenzyme B, leading to the release of methane and a heterodisulfide of the two coenzymes. The latter can be cleaved in an energy yielding reaction. Furthermore, in a process called “reverse methanogenesis,” methane is anaerobically oxidized with sulfate as electron acceptor. This process – known as AOM – is carried out by an uncultured group of archaea (ANME), which has been shown to contain high amounts of a modified MCR (Krüger et al., 2003; Hallam et al., 2003). Hydrogenases are a family of oxidoreductase enzymes that catalyze the reversible oxidation of molecular hydrogen. Nickel-containing hydrogenases have been isolated from bacteria and archaea (Voordouw, 1992). Finally, nickel is also present in a number of other enzymes, such as urease, a superoxide dismutase, and glyoxylases. The functions and biological roles of these metalloproteins have been described in detail (Sigel et al., 2006).

Recently, due to its strong involvement in geologically important microbial reactions, especially methanogenesis, AOM, and carbon fixation, nickel has raised interest as a potential biosignature for these processes and the involved microorganisms in recent or ancient environments (Reitner et al., 2005; Hausrath et al., 2007).

GRN. Gene regulatory network

Introduction

One of the major events in the evolution of multicellular animals was the transition from soft-bodied organisms to those that possessed mineralized hard parts for protection

and support. This major evolutionary hallmark supported the rapid diversification of animals and their occupation of a diverse range of novel ecological niches at the dawn of the Phanerozoic, between 560 and 530 million years ago, when mineralized skeletons appeared relatively synchronous in a variety of Phyla during the so-called Cambrian Explosion (Knoll, 2003; Conway Morris, 2006). However, it is still unclear exactly what drove this sudden capacity to construct mineralized structures, be it changes in ocean chemistry (Brennan et al., 2004) or the evolution of more diverse ecologies (Cohen, 2005), including predators (Vermeij, 1989). Investigation of biomineralization processes will provide insight into the molecular and genetic mechanisms that accompanied the appearance of mineralized body parts during the early Cambrian, shedding light on the processes that generate the diversity of life we see around us today.

Until recently, studies of biomineralization processes were mainly restricted to describing the (ultra)structure of the minerals and their interaction with the organic material provided by the organism (Lowenstam and Weiner, 1989; Mann and Webb, 1989). However, the generation and elaboration of biominerals is ultimately controlled by genes (Jackson et al., 2006, 2007a, b), which must in turn be expressed in the appropriate tissue and at an appropriate stage of development. Understanding the evolution of such biomineralizing genes and the gene regulatory networks (GRNs) in which they act is, therefore, vital to the understanding of how animals evolved and will also provide clues for the fabrication of biomimetic materials.

Biomineralization

Biomineralization refers to the processes by which organisms form minerals (e.g., calcium carbonate, calcium phosphate, silica, iron oxides) under strict biological control. These processes are, therefore, defined as *biologically controlled mineralization*, with the skeletons formed being integral, functional parts of the organisms (Lowenstam and Weiner, 1989). There are, however, several other serendipitous processes linked to living organisms (e.g., microbes) or organic substances that result in mineral (mainly calcium carbonate) formation that are not under strict control of organisms. These processes are termed either *biologically induced mineralization*, where inorganic minerals are precipitated by adventitious precipitation resulting from secondary interactions between various metabolic processes and the surrounding environment (Mann, 2001), or *organomineralization*, a term used to describe mineralization processes that involve organic molecules or particles, whether linked to living organisms or not (e.g., degrading organic matter) (Trichet and Defarge, 1995).

While both *biologically induced* and *organomineralization* play an important role in the formation of carbonate systems in the geological record (e.g., microbialites, stromatolites, ooids) (Reitner and Neuweiler, 1995; Arp,

BIOSILICIFICATION

The biological formation of opal-like amorphous hydrated silica. This phenomenon occurs on a globally vast scale in a wide variety of organisms, including protists, radiolarian, foraminifera, sponges, molluscs, brachiopods, copepods, ascidians, diatoms, and higher plants. See entries “*Silica Biomineralization, Sponges*”, “*Microbial Silicification – Bacteria (or Passive)*” and “*Microbial Biomineralization*” for further reading.

BLACK SHALES

Wolfgang Oschmann
 University of Frankfurt, Frankfurt, Germany

Definition

Most modern and ancient aquatic (marine, brackish, and lacustrine) environments were sufficiently oxygenated to permit colonization by numerous benthic, planktic, and nectic organisms. Due to excess oxygen the biologically produced organic matter is rapidly degraded. The sediments formed thereby exhibit only very low amounts of organic matter.

In contrast, very high rates of primary production and/or stagnant water bodies result in black shale sedimentation, which is associated with oxygen depletion or even lack of oxygen within the substrate and to some extent also within the water column. Degradation of organic matter is incomplete, partly by anaerobic bacteria, causing strong enrichment of organic matter in sediments. Black shales therefore commonly exhibit excellent preservation of organic molecules and mineralized soft tissues and hard parts of organisms.

The importance of black shales for scientists and the society are twofold. Black shales serve as source rocks for fossil fuels (oil and gas), which cover most of the energy needs of modern societies, and due to excellent preservation they provide particular sites for palaeontological studies.

Sedimentary characteristics of black shales

Black shales sediments in common are dark gray to black in color and are characterized by microlaminations, which may vary from distinct to blurred. The lamination is caused by quiet depositional conditions and the scarcity or lack of bioturbation. In many cases, the lamina were formed by alignments of fecal pellets ([Figure 1a](#)), which rained down in great numbers from surface waters. The

Synonyms

Rock Varnish, *Rock Glaze*, *Silica Glaze*, and *Schutzrinde* were introduced in 1891, from a translation of the French term *manteau protecteur*. “*Schutzrinde*” for all dark coatings, including “*Wustenlack*” a thin, polished coating that may be an eolian polished patina; “*Dunkle Rinden*” as a dark brown to black coating, possibly more similar to Sonoran and Mojave desert varnish; and “*Schweinfurth*,” which describes black coatings on rocks in Egypt that have spread on surrounding sands.

Definition

Desert Varnish. In arid environments such as Death Valley (California), rocks are covered with black opalescent desert varnish ([Figure 1](#)). Desert varnishes have been found in all continents, in locations such as the Gobi, Sonoran, Mojave, Namibian, Victorian, and Atacama

DOLOMITE, MICROBIAL

Jennifer A. Roberts, Paul A. Kenward
 University of Kansas, Lawrence, KS, USA

Synonyms

Bacterial dolomite; Organogenic dolomite

Definition

Dolomite. Widely distributed rock-forming mineral, $\text{CaMg}(\text{CO}_3)_2$. Usually, white or colorless, but can be yellowish and brown with rhombohedral crystals exhibiting curved, composite faces. It also occurs with massive and granular habit and has rhombohedral {1011} cleavage.
Dolomitization. The process of converting calcite in limestones to dolomite by the action of magnesium-bearing solutions.

is related with the Snowball Earth scenarios and increase of oxygen in the atmosphere.

EDIACARAN BIOTA

Dmitriy Grazhdankin
 Russian Academy of Sciences, Novosibirsk, Russia

Definition

Ediacaran period: An interval in the history of earth after the Marinoan/Varanger glaciation of the Neoproterozoic Era (see Chapter *Snowball Earth*), but before the Cambrian radiations. This interval marks the introduction of complex macroscopic organisms, leading to a revolution in the structure and evolution of marine paleocommunities, including the establishment of multi-level trophic structures, coevolutionary predator–prey interactions and infauunal activity.

Ediacaran biota: A highly distinctive assemblage of Ediacaran-age macroscopic organisms preserved as casts and moulds in siliciclastic, volcanoclastic, and carbonate sediments.

Introduction

Ediacaran biota is a heterogeneous assemblage representing the earliest known communities of macroscopic organisms. Diverse Ediacaran fossil assemblages are coeval with the earliest phosphatized metazoan embryos (Xiao et al., 1998; but see Bailey et al., 2007; Xiao et al., 2007), the earliest undisputed traces of metazoan activities (Jensen, 2003), and the time of eumetazoan crown-group divergence estimated by some (but not all) molecular clocks (Peterson and Butterfield, 2005). Nonetheless, placing the Ediacaran morphologies into a metazoan phylogeny has been an enduring challenge to paleobiologists (Gehling, 1991; Fedonkin, 1992; Jenkins,

GEYSERITE

A dense, banded or laminated variety of sinter that forms at and near the vents of geysers and some hot springs. See entries “*Sinter*” and “*Hot Springs and Geysers*” for further reading.

GLASS

See entry “*Basalt (Glass, Endoliths)*.”

GLAUCOPHYTES

Glaucoephytes (glaucoecystophytes or glaucoecystids) are colorless freshwater protists containing plastids derived from primary endosymbiosis (see also entry *Symbiosis*) that is, they are still surrounded by a peptidoglycane wall, which may be viewed as reminiscent of their cyanobacterial origin. Previously, these primitive plastids were also called “cyanelles.” For details, please refer to entry “*Algae (Eukaryotic)*.”

GOLD

Veit-Enno Hoffmann
University of Göttingen, Göttingen, Germany

Synonyms

Aurum (Latin)

Definition

Precipitation/Bioaccumulation of gold is the precipitation of fine-grained gold colloids by microbial activities.

Nugget. A natural gold grain (>5 mm, >200 mg).

The impact of the use of microbial activity for the solution and precipitation of gold was undervalued for a long period, thus affording the opportunity for economic and environmentally friendly gold bio-processing. Furthermore, the current high price of gold has led to intensive research into the precipitation of gold.

Some iron and sulfur oxidizers (e.g., *Acidothiobacillus ferrooxidans*, *Acidithiobacillus thiooxidans*) contribute to the disintegration of important gold ores (Nordstrom and Southam, 1997). In an environment of gold-bearing rocks, the dissolved gold content is 40 times higher than in comparable non-gold-bearing areas (Benedetti and Boulègue,

1991). It has been shown that the dissolution of gold is dominated by the gold thiosulfate complex $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ which is composed of the above-mentioned bacteria and Actinomycetes (e.g., *Streptomyces fradiae*) (Nordstrom and Southam, 1997; Sand et al., 2001). However, $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ is only stable until the sulfur-oxidation is complete (Lengke and Southam, 2005). Subsequently the gold thiosulfate complex is degraded by *A. thiooxidans*. Thereby gold accumulates in the form of fine-grained colloids inside the bacterial cell and on the surface of the cell membrane. Comparable with the results of Southam and Beveridge (1996) with *Bacillus subtilis* 168, hexagonal-octahedral gold crystals are generated out of the colloids after some months (Figure 1).

As a result of the toxicity of an increasing content of ionized gold, most of the microorganisms that can generate gold die on accumulation of gold. However, various microorganisms, such as bacteria (e.g., *Escherichia coli*, *Pseudomonas maltophilia*, *Plectonema boryanum*), Archaea (e.g., *Pyrococcus furiosus*), Actinomycetes (e.g., *Streptomyces cinamonensis*), fungi (e.g., *Neurospora sitophila*, *Fusarium oxysporum*) and yeasts (e.g., *Endomycopsis fibuligera*, *Sporobolomyces salmonicolor*) from different environments (e.g., hydrothermal, supergene), are partially resistant to the toxicity induced by the accumulation of gold (Kashefi et al., 2001; Nakajima, 2003; Lengke et al., 2006). These bioaccumulation processes are related to various microbial activities (e.g., detoxification, energy generation, passive adsorption). In the laboratory, *Pseudomonas aeruginosa* biofilms demonstrate a higher resistance to the toxicity of gold than planktonic *P. aeruginosa* cells and form solid gold at the base of the biofilms (Karthikeyan and Beveridge, 2002). Reith et al. (2006) isolated a 16SrDNA sequence from natural samples. This sequence was only found on gold grains

Gold, Figure 1 A secondary electron (SE) image of a hexagonal gold crystal from the secondary gold deposit Silberkuhle near Korbach, Germany.

shortly after the extreme glaciations during the late Neoproterozoic (Hoffman et al., 1998) and was nearly synchronous with the rapid evolutionary pulse that coincides with the Ediacaran and Cambrian radiations. Final assembly of Gondwanaland and a circum-Gondwanaland mountain chain is thought to have provided nutrients to the oceanic realm and also resulted in a large $^{87}\text{Sr}/^{86}\text{Sr}$ spike due to the erosion of the mountains (Squire et al., 2006). Therefore, links between the assembly of the Gondwanaland supercontinent and biological evolution are forwarded by numerous studies (Meert and Lieberman, 2008).

GREAT OXYGENATION EVENT (GOE)

The term “Great Oxygenation Event” (GOE, also known as “Great Oxidation Event,” “oxygen catastrophe,” or “oxygen crisis”) describes a critical environmental change in Earth history that resulted from the appearance of diatomic oxygen (O_2), a waste product of oxygenic photosynthesis, in the atmosphere. The GOE occurred around 2.4 billion years (Ga) before present, close to the boundary between the Archean and the Proterozoic (2.5 Ga). For details, please refer to “[Critical Intervals in Earth History](#).”

GREEN ALGAE

Green algae are photosynthetic eukaryotes with simple plastids (derived from primary endosymbiosis) that are mostly microscopic and rarely more than a meter in greatest dimension. The approximate 6,000 extant species show an enormous diversity of growth habit and fine details of their cellular architecture. Green algae occur as unicellular or colonial, microscopic or macroscopic, motile planktonic, as well as benthic attached forms. Some (e.g., Dasycladales) are important carbonate producers in aquatic environments, others live in symbiotic associations with fungi to form lichens in terrestrial settings. Green algae living as endosymbionts inside heterotrophic organisms are a common phenomenon. The order Charales, in which full tissue differentiation occurs, is considered to include the closest relative of higher plants. For details, please refer to entry “[Algae \(Eukaryotic\)](#).”

GUILD

Metabolically related populations, e.g., sulfate-reducing microorganisms. See entry “[Microbial Communities, Structure, and Function](#)” for further reading.

H

HABITAT

The physical location or dwelling place of a particular organism, where an individual ecotype can be found or isolated from. See entry “*Microbial Communities, Structure, and Function*” for further reading.

HALOBACTERIA – HALOPHILES

Helga Stan-Lotter
University of Salzburg, Salzburg, Austria

Definition

Halobacteria (plural), *halobacterium* (singular). Colloquial for halophilic archaeobacteria (or archaea), which are single-celled life forms. Synonyms: Haloarchaea (plural), haloarchaeon (singular).

Halobacterium. The name of a genus of the archaeal family *Halobacteriaceae* (Grant, 2001).

Halophilic. Requires a salt-rich environment for growth and survival.

Introduction

Saline waters dominate the earth, with the oceans holding 97% of the planet's water (a total of 1.338×10^9 km³; <http://ga.water.usgs.gov/edu/earthwherewater.html>). Saline inland seas, groundwater, and saltwater lakes hold another 0.9–0.94%, which exceeds the volume of the world's available freshwater ($\sim 1.1 \times 10^7$ km³). The definition of a hypersaline environment is one that possesses a salt concentration greater than that of seawater (>3.5% w/v). Water-containing environments are usually described as thalassohaline or athalassohaline (see

Chapters “*Saline Lakes*,” “*Soda Lakes*”). Thalassohaline waters are marine-derived and therefore contain, at least initially, the seawater composition; with increasing evaporation, the concentration of various salts is changing. Athalassohaline waters may also receive influx of seawater; however, the chemical composition is mainly determined by geological, geographical, and topographical parameters.

Interactions between halophilic microorganisms and geological materials have been recognized early in the history of mankind and continue to impact human endeavors, including the exploration of energy sources, the storage of waste, the search for extraterrestrial life (see Chapter “*Deep Biosphere of Salt Deposits*”). For example, the evaporation of seawater for the purpose of making salt and the concomitant development of red color of brines, which is due to pigmented microorganisms, have been described already 2,700 years ago (Oren, 2002). It was also observed early that the presence of microorganisms in solar salterns enhances the precipitation and the yield of salt (Oren, 2002). Halite, the mineral of sodium chloride, primarily forms from the evaporation of seawater. Subsurface deposits of halite occur in many areas and are far more abundant than was previously recognized. The advent of widespread oil drilling revealed a frequent association of ancient salt deposits and the presence of the biogenic energy sources, oil and methane (Sassen et al., 1994). The potential impact of viable halophilic microorganisms in salt deposits (see Chapter “*Deep Biosphere of Salt Deposits*”), some of which are being used as storage sites for long-lived radioactive isotopes such as transuranic wastes, has been the focus of much research. The striking discovery of extraterrestrial halite in meteorites (see Chapter “*Deep Biosphere of Salt Deposits*”) and recently, in salt pools on Mars (Osterloo et al., 2008) make a search for halophilic microorganisms on other planets or moons plausible.

ORGANIC CARBON

Carbon that occurs in materials of ultimately biological origin that can be oxidized. Organic matter is material that contains organic carbon. See entries “[Carbon \(Organic, Cycling\)](#)” and “[Carbon \(Organic, Degradation\)](#)” for further reading.

ORGANOMINERALIZATION

Christian Défarge
 Université d'Orléans and Université François-Rabelais de Tours, Orléans, France

Synonyms

Organomineral formation

REMINERALIZATION (OF ORGANIC MATTER)

Degradation of organic matter that results in net conversion of organic carbon to inorganic (oxidized) carbon species such as CO_2 or HCO_3^- . See entries "[Carbon \(Organic, Cycling\)](#)" and "[Carbon \(Organic, Degradation\)](#)" for further reading.

RHODOPHYTA

The Rhodophyta, also referred to as "red algae," are a distinct eukaryotic lineage of algae with simple plastids (two membranes, derived from primary endosymbiosis). Rhodophytes have a long geological record since the Mesoproterozoic (1.2 Ga). Today, they encompass about 670 largely marine genera with up to 4,500 species predominating the coastal and continental shelf areas of tropical, temperate, and cold-water regions. Red algae are significant as primary producers and providers of structural habitat for other marine organisms. Calcifying (coralline) red algae play an important role in the primary establishment and maintenance of limestone reefs. For further details, see entry "[Algae \(Eukaryotic\)](#)."

RNA-WORLD

The term "RNA-World," first suggested by Walter Gilbert in 1986, describes a popular concept on a hypothetical early stage in the origin of life on Earth. Based on discoveries of enzymatic activities in microbial ribonucleic acids (RNA), a system was suggested where primordial RNA molecules accounted for both, the storage of genetic information and catalytic functions necessary to assemble themselves in a primitive self-replicating system. The RNA molecules evolved in self-replicating patterns, using recombination and mutation to explore new functions and to adapt to new niches (Gilbert, 1986). Such a system would not have required the presence of DNA and/or protein enzymes for biochemical reactions. For further reading, please refer to "[Origin of Life](#)."

SKELETON

Biologically, a skeleton is a hard or rigid framework that could provide protection and support in many types of organisms. Most of skeletons are mineralized, but some may not be mineralized (e.g., some annelid tubes being agglutinated). They could be subdivided into exoskeletons and endoskeletons, not including hydroskeletons. Exoskeletons are external hard parts. They may enclose the soft tissues and organs of the body, or may be external sclerites. Endoskeletons are internal hard parts (typical of many vertebrates). Most of endoskeletons are generally surrounded by skin and musculature. See entry "[Animal Skeletons, Advent](#)" for further reading.

SMALL SHELLY FOSSILS

Small shelly fossils (SSF, also "Small Shelly Fauna") is a non-taxonomic term, first used by Matthews and Missarzhevsky in the title of their review paper in 1975, to denote the earliest skeletal fossils, although some of these fossils may not be small and most of them are actually not shells. It has been popularly used in literature somewhat as a catchall term for the early Cambrian skeletal fossils, including spicules, shells, tubes, and diverse disarticulated sclerites. See entries "[Animal Skeletons, Advent](#)" and "[Critical Intervals in Earth History](#)" for further reading.

SNOWBALL EARTH

Paul F. Hoffman
Harvard University, Cambridge, MA, USA

Synonyms

Cryochron; Global glaciation; Hard snowball; Ice-albedo catastrophe; Snowball (in geology); White Earth

Definition

Snowball Earth is a climate in which the oceans and most land areas are permanently covered by glacial ice. As less sunlight is absorbed by ice than by water or land, a critical area of ice will cause surface temperatures to fall below freezing everywhere, resulting in a snowball Earth. This arguably occurred near the beginning and end of the Proterozoic eon. Snowball Earths self-destruct after millions of years due to the buildup of atmospheric carbon dioxide of volcanic and metamorphic origin, which could not be converted into organic matter or limestone. Biological evolution is a postulated cause and consequence of snowball episodes.

History of the concept

Sedimentary deposits of glacial origin were first described from the late Proterozoic (Neoproterozoic) of Scotland in 1871 and from the early Proterozoic (Paleoproterozoic) of Canada in 1907. By 1940, it was apparent that the Neoproterozoic glaciation(s) had been more extreme than those of the Pleistocene and at least equal in severity to the late Paleozoic glaciations of Gondwanaland. In the 1960s, the occurrence of glacial deposits within thick successions of nearly pure carbonate strata suggested that Neoproterozoic ice sheets had entered what were normally the warmest parts of the globe. This was confirmed in the 1980–1990s by reliable paleomagnetic data showing that ice sheets had reached the ocean close to the paleoequator in the Neoproterozoic of Australia and Paleoproterozoic of South Africa (Evans, 2003). Moreover, evidence of marine geochemical anomalies concurrent with glaciation came increasingly to light in the form of sedimentary Fe_2O_3 and MnO_2 ore deposits, large excursions in stable carbon and sulfur isotopic compositions of minerals precipitated from seawater, and distinctive post-glacial "cap" carbonate sediments that rest directly on the terminal glacial deposit at all latitudes (Hoffman and Schrag, 2002). Neoproterozoic glacial deposits are now known from 22 different paleocontinents and microcontinents, and Paleoproterozoic deposits from 6.

The fraction of incoming solar radiation absorbed by ocean water under cloudless skies is 0.9, but for continuous ice it is only 0.4–0.6 and as low as 0.1 if the ice is covered by fresh snow. In the 1950–1960s, calculations by meteorologists of zonal average surface temperatures at different latitudes, assuming radiative energy balance and incorporating crude parameterizations of the radiative effects of clouds, meridional heat transport, and positive feedbacks due to the reflectivity (albedo) of ice, suggested that a lowering of solar luminosity by a few percent would result in a globe-encircling glaciation, or "white" Earth (North, 1990). If the luminosity is incrementally lowered, polar ice caps expand until their edges reach a critical latitude, beyond which ice advances rapidly to the equator without any additional luminosity reduction, or even with increased luminosity. This is due to runaway ice-albedo feedback – more ice reflects more radiation, creating more ice. (The same calculations indicated that a small increase in radiative forcing, due to anthropogenic CO_2 emissions for example, could cause a sudden loss of polar sea ice at a critical $p\text{CO}_2$ threshold.) These sensational findings greatly stimulated the nascent field of climate modeling, but proponents were puzzled how a "white" Earth disaster had been averted given that solar luminosity has increased by 25–30% over geological time (the so-called faint young Sun paradox). They assumed (incorrectly, as it turned out) that such an occurrence would extinguish all life – deep-sea chemoautotrophs and polar extremophiles were then unknown – and would be permanent because of the very large increase (~25%) in radiative forcing required to overwhelm a "white" Earth's high albedo.

SPECIES (MICROBIAL)

Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization; thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy. See entry “*Microbial Communities, Structure, and Function*” for further reading.

SPELEOTHEMS

Roman Aubrecht
 Comenius University, Bratislava, Slovakia

Synonyms

Cave deposits; Cave sinters

Definition

The word “speleothem” is from Greek and means “cave deposit.” According to its origin, this term can be used for any cave deposits, but it is used mostly for secondary mineral deposits formed (precipitated) in caves. In this entry, speleothem is understood as constructively formed, new cave material. Materials originated by destructive phenomena, such as erosion, weathering, etching, biocorrosion, or bioerosion are not subjects of this entry.

Biogenic and abiogenic speleothems

Most of the speleothems originate inorganically by precipitation of various minerals from solutions. The minerals are dissolved by undersaturated fluids and precipitate when the solutions become supersaturated, e.g., by evaporation, outgassing, or pH changes. Mineralogical compositions of speleothems vary depending on the environment in which the caves are formed. The most common speleothem-forming mineral is calcite (as most of the caves are formed of limestones), forming well-known sinter forms, such as dripstones (stalactites, stalagmites) and flowstones. Locally, mostly in hydrothermally influenced cavern systems, speleothems may be formed by its rhombic modification – aragonite. Gypsum and other sulfate minerals commonly form speleothems in gypsum karst but are widespread also in other types of caves. Speleothems formed in silicate rocks (e.g., sandstones, quartzites, granites, etc., [Figure 1](#)) are relatively rare, composed mostly of various forms of silica (from opal-A to microquartz depending on its recrystallization). Other speleothems can be represented by ferroan and manganese oxides and hydroxides forming cave flowstones.
